Yeast Research.—To summarise in a critical fashion the salient features of existing knowledge in a particular sphere of activity is no easy matter, but, once successfully accomplished, cannot be other than useful. A recent paper by Dr. L. H. Lampitt (*Jour. Inst. of Brewing*, **36**, p. 250; 1930) may be said to fall in this category, and should provide food for thought for scientific workers whether they are interested in yeast from the practical or academic point of view. After a brief sketch of the classical work of Pasteur, Büchner, Harden, and others, the problem of the acceleration of fermentation by substances which can act as acceptors for hydrogen is discussed. The anomalous behaviour in this respect of sodium arsenate is noteworthy in view of recent work on the possibility of replacing phosphates by arsenates in the cycle of changes accompanying fermentation. Reference is also made to the effects on yeast activity of antiseptics, and in this connexion attention is directed to the fact that the study of maltase, which is readily crippled by phenol, has been comparatively neglected in recent years. Fernbach's selective fermentation of dextrose and lævulose and the theoretical deductions arising therefrom are also discussed. Other starting-points for investigations include the effects of radiations on the growth of yeast, the nitrogen question (NATURE, **125**, p. 105; 1930), yeast-enzymes and the existence of bios, and the nature of the yeast-substance. It is pointed out that the confusion arising from many of the existing results is due chiefly to lack of standardisation of the experiments, and it is suggested that such results should always be confirmed by direct experiment before an investigation is started. It is interesting to note that Dr. Lampitt regards the production of carbon dioxide as the only true criterion of fermentation.

Researches on Globin.—The *Comptes Rendus du Laboratoire Carlsberg*, vol. 18, No. 4 (1930), contains a communication by Roche on the above subject. The author has confirmed the experiments of Hill and Holden, published in 1926, on the decomposition of hæmoglobin by dilute acids; the product is called paraglobin, and is regarded as different from denaturated globin. The *p*H value of natural globin is 7·5-7·6, as determined by cataphoresis. Natural globin and hæmatin form alkaline methæmoglobin, which was prepared in several other ways. The combination of a natural globin from various animals takes place with any hæmatin. The isoelectric point of paraglobin is 7·6-7·8, by cataphoresis. It shows a minimum solubility in a pure solution over the range of *p*H 6·6 to 8·4. The variations found by other authors are due to degradation of the protein in their experiments. Paraglobin forms with hæmatin cathæmoglobin, but this reaction is specific for the globin, since it does not occur with other proteins. Boiling with acid (*p*H 2-4) for a short time does not alter the isoelectric point or solubility of paraglobin, but with *p*H 7·0 it is coagulated, and is then insoluble in strong acid or alkaline media. This form is called denaturated globin. Pepsin has an optimum action on paraglobin at *p*H 2·2, trypsin at *p*H 8·2, in opposition to the results of Northrop. Trypsin does not act unless kinase is present. Pepsin liberates COOH and NH_2 in the ratio of unity. The first action of pepsin or trypsin causes modifications indicated by a movement of the isoelectric point towards more acid values of *p*H. Since this is also found in the action of the hydroxide ion, it is suggested that both changes, at the commencement, have the same mechanism.

Denaturation of Proteins by Urea and Related Substances.

By Sir F. GOWLAND HOPKINS, F.R.S.

'DENATURATION', though a phenomenon familiar objectively to all who handle proteins, involves a change of state of which the precise nature is yet obscure. The term itself is scarcely capable of adequate definition. It is only certain that native proteins dispersed in water as lyophil colloids suffer, as the result of diverse alterations in their environment, a change which is accompanied by complete loss of solubility in pure water or dilute salt solutions. If under any influence (such as that of dilute acids or alkalis) a protein denatured in this sense is retained in solution, or redispersed after separation, it is then found no longer in the lyophil but in the lyophobe condition. Denaturation thus understood is always antecedent to coagulation or flocculation, these being secondary processes dependent upon conditions which make for instability in suspensoid systems. We are quite ignorant of the nature of any molecular change which may be responsible for, or accompany, this change in the type of dispersion. Evidence suggesting that some intramolecular readjustment does, as a matter of fact, occur will be mentioned immediately.

A special interest is attached to the change of state involved in denaturation because its occurrence appears to be characteristic of the protein molecule when it is intact. It is apparently not undergone by even the most complex of its degradation products; this circumstance tends to justify the view, based also on other evidence, that the molecular structure of an intact protein has features differing from, or added to, those of a complex polypeptide.

It is well known that in albumins, globulins, and a number of other native proteins in solution, denaturation is induced by heat, by certain forms of radiation, by the action of relatively strong acids and alkalis, by adsorption at surfaces or in films and mechanically by shaking. Such proteins are also denatured when under defined conditions they are precipitated from solution by such agents as alcohol or acetone.

It has recently become known that these diverse methods of denaturation all produce, in addition to the colloidal change, a shift in the relations of sulphur within the protein molecule, such that the denatured product yields, in some cases directly, and in others after treatment with a reducing agent, a reaction characteristic of the thiol group. This is not given by the native proteins. This characteristic happening was first observed by Heffter in 1909, though he did not specially relate it with the events of denaturation. The relation has since been more fully established.[1]

An influence, seemingly quite different from those already mentioned but resulting in typical denaturation, is exerted by urea (and, as will be immediately indicated, by other related substances) when added in high concentration to native protein solutions.

This phenomenon has received but little attention until recently. So far back, indeed, as 1900, K. Spiro[2] directed attention to it. His experiments, however, were in the main concerned only with the effect of urea and certain other amides and organic bases in preventing the heat coagulation of proteins or in raising their coagulation temperatures.

Anson and Mirsky[3] have recently pointed out that urea in concentrated solution can denaturate hæmoglobin, egg albumin, and serum albumin, and that it also dissolves the denatured protein. Hsien Wu has devoted several recent papers to a study of denaturation and has observed that some denatured proteins are soluble in urea solutions, while with Huang he has taken advantage of this circumstance to determine their molecular weight, finding that "denaturation *per se* does not necessarily involve a change in molecular weight". Dill and Allsburg employed urea solutions as solvents for a protein insoluble in water. Burk and Greenberg[4] have used them in order to determine the molecular weights of proteins at their isoelectric point, and to decide whether they are capable of undergoing changes in their state of aggregation with changes of solvent. They found that hæmoglobin and egg albumin are denatured by urea, and that the former has, in urea solutions, only half the molecular weight indicated in aqueous solution. These authors refer incidentally to the circumstance that formamide, urethane, and thiourea act in solution similarly to urea though not so effectively. Owing to their particular aims, the work of the authors quoted has involved the use of urea solutions as denaturants and solvents rather than a study of the conditions and rate of the changes induced by such agencies.

The following preliminary and descriptive account of certain observations of my own (some were made so far back as 1899, though now extended) will suggest, I think, that the mechanism of this form of denaturation is worthy of close study.

The experiments have dealt with ovalbumin and with serum proteins. It will be convenient to deal first with the former, which has been more fully studied.

EGG ALBUMIN.

Pure egg albumin, twice recrystallised by the method of Hopkins and Pinkus and its solution afterwards dialysed until wholly free from ammonium sulphate, was the material usually employed. At the end of dialysis, the *p*H of such a solution is invariably within the range of 4·8-4·9.

If in a few cubic centimetres of such a solution urea be dissolved (say 0·1 gm. per c.c.; though the amount is unimportant) and the solution evaporated to dryness in a vacuum desiccator at room temperature, the urea may then be extracted from the residue with water, while the protein will be found to be wholly insoluble, forming a cast of the urea crystals which separate on evaporation. The *p*H of the mixture may be adjusted from, say, 4·0 to 7·0 without any difference in the result. If the washed protein residue be now ground up with a few small crystals of sodium nitroprusside and a drop or two of weak ammonia added, a deep red-purple colour characteristic of a sulphydryl reaction immediately develops. If ordinary egg-white be diluted, filtered, and similarly treated, it behaves as described whether at its original *p*H (7·5 to 8·0) or when brought to *p*H 4·8.

The above simple method is a convenient means for deciding whether or not a given substance exerts a denaturing influence upon proteins. Using the pure albumin a number of substances were thus tested. Positive results were given by methyl-, ethyl-, and butyl-urea; by unsymmetrical dimethyl- and diethyl-urea; by thiourea; by acetamide, formamide, and by urethane. Wholly negative were the effects of symmetrical diethyl-urea, of acetyl-, and methyl-acetyl-urea; of biuret, allantoin, and semicarbazide; of alanine, phenyl alanine, valine, leucine, and cystein; of benzamide; of creatine, caffeine, and asparagine. Also negative was found to be the effect of a number of other nitrogenous compounds more remote from the active amides.

Results so obtained are with ovalbumin quite unequivocal. The residue obtained on evaporation is either completely resoluble or the protein is manifestly denatured. When washed free from the denaturant the denatured protein yields a nitroprusside reaction in all cases, while none is given by the solution when the protein residue remains soluble.

Most of the above denaturants are but slightly dissociated in solution, and in other cases adjustment of the pH to near neutrality has no effect on their behaviour. It is clear that denaturation on these lines does not depend primarily upon the influence of hydrogen or hydroxyl ions.

To some degree at least, relations between constitution and denaturating power would seem to hold. An amide structure is apparently necessary, but in certain relations its activity is lost. Among the ureas, mono-alkyl substitution, or unsymmetrical di-alkyl substitution, leaves the activity qualitatively intact. Symmetrical di-alkyl ureas, on the other hand, are inactive ; one amino group must apparently remain unsubstituted. To judge from the case of acetyl urea, however, mono-acyl substitution removes the activity. In biuret, allantoin, and semicarbazide activity is also lost. Acid amides (acetamide and formamide) are active, but all amino acids tried were without effect, and likewise asparagin. Noteworthy is the activity of urethane. Bases of the type of creatin or caffeine are inactive.

More detailed aspects of the events involved in denaturation on these lines are to be observed in solution. If a solution of the pure protein is fully saturated with urea (1 gm. per c.c.) at room temperature, it will be found to give a well-marked nitroprusside reaction immediately. Even before the solution has recovered from the depression of temperature due to the solution of the urea the colour reaction is marked. By the time that room temperature is reached it becomes, in the case of moderately high concentrations of protein (4-5 per cent) intense. It can be observed to increase during the following half-hour or so.* The establishment of a reactive thiol group in the protein molecule is thus a rapid process, and quantitative evidence of the simultaneous occurrence of a colloidal change will be given later.

If the urea-protein solution is exposed to the air, the thiol group is slowly oxidised. It is restored, however, by reducing agents and the colour reaction immediately reappears if the solution be first treated with cyanides (see later). Its behaviour in the denatured protein is the same, therefore, as in cysteine, glutathione, etc.

Since urea exerts not only a denaturating action, but also a dispersive action upon the denaturated protein, the behaviour of an albumin solution, when urea is added to it, will vary in detail not only with the absolute but also with the relative concentrations of the two constituents. The data in the following table will be sufficient to illustrate the observed effects as modified by concentration variations. The strongest protein solution had a pH of 4·9, which shifted to 5·8 on saturation with urea. The small variations at other concentrations were insufficient to affect the results.†

It will be seen that though denaturation itself is more rapid with the higher concentrations of urea (see below), the dispersive action may prevent or delay the separation of a precipitate or gel which occurs at lower concentrations. Whether gel or precipitate shall result seems to depend essentially on the rate of separation. It may be said that an identical experiment was simultaneously carried out at 37° C. with little difference in the results save that the gel formation was somewhat faster. Needless to say, any considerable modifications in the concentrations will affect the time relations as given in the above table.

Concentration of Original Protein Solutions (per cent).	Amount of Urea added. (per cent Saturation).	Condition after standing for the intervals given. Temp. 22° C.					
		Immediately.	½ Hour.	1 Hour.	2 Hours.	5 Hours	20 Hours.
7	100	No visible change	→	Increasing	Viscosity	→	Fragile gel.*

	30	Ditto	..	..	Cloud	..	Definite precipitate.

* On longer standing firm gels.

Rapid gel formation can be observed in the case of still stronger albumin solutions and an easy demonstration of the potency of urea as a denaturant is so obtained. If 5 c.c. of undiluted egg-white, which has been first whipped to destroy the membranes and squeezed through muslin, be placed in a test tube and 5 gm. or a little less of urea, finely powdered to facilitate solution in the viscous material, be added, the mixture will begin to gelatinise almost as soon as the urea has dissolved. In fifteen minutes or less at room temperature a firm gel is obtained of which a

* To observe the full colour, relatively high concentrations of the nitroprusside should be used. Twenty to thirty milligrams of the solid, for example, dissolved in 5 c.c. of the solution. It is then made alkaline with ammonia.

† Throughout this notice the concentrations of urea, because they are generally so high, are for convenience reported not in terms of molarity but as percentages of complete saturation at 17° C. (1 gm. per c.c.). The results can thus be reproduced without reference to volume changes consequent upon adding varying amounts of urea to the protein solutions. The concentrations of albumin referred to are those of the original solution ; those actually present in the urea-protein mixtures vary therefore with the amount of urea added. It will be found that all essential conclusions are unaffected by this circumstance ; the observations upon which they are based being comparative. The actual concentration of protein in a solution saturated with urea is given approximately by multiplying that of the original solution by 0·55, and in a solution 60 per cent saturated by 0·70.

portion, if soaked in a solution of sodium nitroprusside, will develop on its surface a strong purple colour.

The gels, which result from the denaturation of the pure albumin, display many characters of interest. Though containing so high a concentration of urea, they are optically completely homogeneous and transparent, resembling in appearance pure silica gels. When treated with successive quantities of water until the urea has wholly diffused out of their structure they become slightly opaque, but they display great resistance to sol formation. When they are heated with excess of water the amount of protein found in the sol phase is, no matter what the temperature, negligibly small. Remarkable is the behaviour of an original gel, still containing the urea, when alternately cooled and warmed. If the flask or test-tube containing such a gel be placed on ice, its mass becomes pervaded with silky crystals of urea. If it now be allowed to return to room temperature or even if it be rapidly warmed to higher temperatures, it completely regains its homogeneous transparent appearance, and in the case of a well-formed gel without displaying at any moment the least sign of increased fluidity. The vessel containing it can be placed in a boiling water bath without producing any effect upon its visible characters. Gels formed originally within certain ranges of protein or urea concentration may require to be cooled to a degree or two below 0° C. before the urea separates as described and should be placed for a few moments in an ice-salt freezing mixture.

With regard to the effect of such internal crystal formation upon the ultimate structure of gels, Moran and Hardy have studied what is clearly a somewhat different case, namely, the formation and disappearance of ice crystals in aqueous gelatin gels when respectively frozen and thawed. These authors discuss the effect of the crystal formation upon the ultimate gel structure. Hardy found, though only in the case of gels much more concentrated than those dealt with here (20 per cent gelatin and upwards), that the capacity of the gel for re-adsorbing water is so great that after thawing, the spaces occupied by the ice crystals vanish "almost entirely" though the collapsed walls of such spaces do not join together. With lower concentrations of gelatin the final result is an open sponge. Hardy also found that the gel, while originally singly refractive, became doubly refractive after freezing and thawing. Evidence for such effects upon the gel structure has proved difficult to obtain in the case of the urea-protein gels by ordinary microscopic study, with or without polarised light. Doubtless a more highly developed technique may be necessary for the purpose. No ice crystals are associated with the urea crystals: separation of the latter within the gel will commonly occur at temperatures somewhat above 0° C. A study of these urea-protein systems may, I think, prove important with respect to gel structure.

When in any circumstances the denatured protein separates not as a gel but as a precipitate, it is found to be insoluble in hydrochloric acid of any strength, and is only very slowly dispersed in alkalis. On the other hand, in a saturated solution of urea it is dispersed to a clear sol.

If an albumin solution, after admixture with urea in effective quantities, be diluted or dialysed at any stage before a precipitate or gel has formed spontaneously, the denatured product is precipitated. A precipitate is obtained almost immediately after the urea has been added, but the amount becomes, of course, greater with the progress of denaturation. Precipitation does not occur, however, if the pH of the mixed solution is appreciably greater than 6·0. When thoroughly dialysed solutions of the crystallised albumin are employed as in most of the experiments under discussion, one effect of adding pure urea in the amounts employed is to shift the pH from 4·8 to ± 5·8.‡ In these circumstances the precipitation of the denaturated albumin on ten-fold dilution of the solution or on dialysis is nearly complete. If, however, before or after the addition of urea the pH is brought to 6·5 or higher by the addition of minute quantities of alkali, no precipitation occurs. If, on the other hand, such a solution be dialysed until all urea is removed (the pH being thereby somewhat reduced) the denatured protein present is found to be in typical suspensoid or lyophobe solution. The urea-free solution is precipitated by salts in minute concentration and the negatively charged particles obey the rule of Hardy. Needless to say, the charge may be reversed by shifting the pH to the acid side of the isoelectric point. It may be mentioned that when weak solutions of albumin containing high concentrations of urea are allowed to stand for three or four days some form of stabilisation may be observed. Clear suspensoid solutions may then be obtained on dialysis when the pH of the original mixture was less than 6·0. The particles then carry a positive charge.

‡ Such a change in pH seems in the circumstances to be unduly great. All estimations were made with the quinhydrone electrode. My colleague, Dr. M. Dixon, has since suggested to me that a chemical action of urea upon the quinhydrone might lead to error. With the hydrogen electrode, however, a shift of the same order is observed. The values obtained with the quinhydrone are perhaps 0·2 of a pH unit too high.

(*To be continued.*)

Norwegian Contributions to the Geology of Spitsbergen.*

DURING every year between 1906 and 1926, Norwegian State-aided expeditions have been at work in western and central Spitsbergen. Of nineteen out of the twenty-one expeditions the geologist, Adolf Hoel, was the leader or joint-leader, and he has prepared, as the first of the long series of *Skrifter* on Spitsbergen or Svalbard, an account of the whole series with summaries of the routes and the work undertaken, maps showing the journeys and the areas surveyed, and appendices on the topographic and hydrographic work.

This memoir will be a great aid to those using the special reports, of which six new contributions are issued along with it. They make an important addition to the geology of Spitsbergen. Hans Trebold has written two memoirs on the Mesozoic rocks, and shows that the Jurassic is represented by the Upper Lias and all the stages from the Lower Callovian to the Upper Volga Beds, which are equivalent to the Purbeck and Lower Wealden of England and the Tithonian of Central Europe. The sequence is then continued through the Lower Cretaceous up to the Aptian. This long succession is nearly all marine, though there are two local developments of estuarine or fluviatile beds with land plants. The author carefully discusses the geographical relations of these beds and the nature of their faunas. He discusses the

* Det Kongelige Departement for Handel, Sjøfart Industri, Handverk og Fiskeri. Norges Svalbard- og Ishavs-Undersøkelser. Skrifter om Svalbard, og Ishavet. Nr. 1, 19-24. (Oslo: Jacob Dybwad.) 10, 3, 2.50, 4, 15, 3, and 3.50 Kr.

two explanations that have been advanced, that of Neumayr, who considered the special features due to climatic influences, and that of Pompeckj and Salfeld, who explained them as the result of life in an isolated sea with unusual physical peculiarities. The author considers that the fauna was mainly controlled by growth in a special sea in which there was great continuity of evolution. He says that the isolation which he accepts is quite different from that contemplated by Pompeckj and Salfeld.

That complete separation from the other seas would affect its inhabitants is undoubted; but in view of the parallel development of the faunas in the Spitsbergen sea with those that lived farther south, some frequent connexions appear to have taken place. The peculiar features of the Spitsbergen fauna, when compared with those of England, the Mediterranean and the Himalaya, appear to indicate the influence of a colder climate than that enjoyed by the Jurassic areas farther south.

Hans Trebold has also written *Memoir*, No. 21, a description of the Valanginian Ammonites of Spitsbergen, a fauna which is similar to that of the Petchora basin in north-eastern Russia and has some of the species found in the Specton Clay of Yorkshire.

The most remarkable addition to palæontology in this series of memoirs is the rich fauna of fossil Acanthaspid fish described by Anatol Heintz from the Downtonian. He includes that formation in the Lower Devonian, but it has been usually regarded as uppermost Silurian. The fauna described in the first *Memoir*, No. 22, is from Ice Fiord, and it includes three new families and seven new genera. The type of the new genus, *Jækelaspis*, is a species described by Ray Lankester as a *Cephalaspis* and by Sir Arthur Smith Woodward as an *Acanthaspis*. The affinities of these fish have been uncertain. Lankester and Sir Arthur Smith Woodward regarded them as belonging to the primitive class of Agnatha; but Traquair referred them to the fish as Dipnoi and members of the Arthrodira. That view is adopted by Herr Heintz. The second *Memoir*, No. 23, describes some additional new species of Acanthaspids, including a remarkable new form, *Huginaspis broggeri*, from the Downtonian of Wijde Fiord in north-western Spitsbergen. These two memoirs form a material addition to knowledge of this group.

The other Palæozoic fossil described in this new series is a simple coral, *Caninia* (*C. callophylloides*, Holtedahl sp.), from the Carboniferous of Ice Fiord. The coral is described in detail by F. Heritsch, and he clearly states the relations of the genus to *Zaphrentis*. The largest radius in the biggest specimen is 27 mm. There is nothing in this coral to call for any special climatic conditions in the Arctic Sea at the time of its existence.

Experiments in the Sea on Antifouling Paints.

PROF. J. H. ORTON (*Jour. Mar. Biol. Assoc.*, N.S., vol. 16, No. 2, 1930) describes the results of a series of experiments, extending over a period of three and a half years, to test the power of a number of paints and other substances (fifteen in all) to inhibit the growth of marine organisms, their preservation value, and their durability in sea water. The experimental material included proprietary antifouling and anticorrosive paints and was tested in seven different habitats in three different localities on wood and on shells. Observations were also made on the growths on ships' bottoms, piers, buoys, and rafts.

It was found that the fundamental factors determining the capacity of a paint to prevent growths include (*a*) capacity to adhere to a surface, which in practice may be slightly damp; (*b*) capacity to resist erosion; and (*c*) the possession of a toxicity depending upon slow but efficient ionisation of toxic substances. It is proved by critical chemical analyses that gradual loss of toxicity of the more efficient poisonous paints was accompanied by gradual diminution of the toxic elements, arsenic, copper, and zinc, in the paints. Antifouling paints exposed to strong light permit the growths much sooner than in subdued light, but, in the former case, the growth is marine algæ. It is not clear whether this phenomenon is due to the loss of toxicity in the paint due to the direct action of light, or to a greater resistance of the spores of marine algæ to toxic agents.

The preserving value of antifouling substances was also investigated, and it is shown that, for wood at least, coal-tar and black varnish have superior preservative properties to red oxide of iron, the commonest and most widely used anticorrosive paint for the bottoms of iron ships. Coal-tar and black varnish will preserve wood against *Chelura* and *Limnoria*, but not against *Teredo*, to an extent at least equal to that ensured by red oxide, but, on the other hand, they give innocuous surfaces on which marine growths establish themselves more readily than on untreated wood.

The composition of an ideal antifouling paint is discussed and the conclusion reached that if the bottoms of ships are to be maintained free from growths for a period stated in years, some other method must necessarily be used than the application of paints, owing to the comparatively rapid disintegration of the matrix of the paint due to the action of bacteria.

Ceylon Pearl Fisheries.

A MOST interesting memoir entitled "The Pearl Fishery of 1925" by Dr. Joseph Pearson, assisted by Mr. A. H. Malpas and Mr. J. C. Korkham, is given in the *Ceylon Journal of Science* (Section C, Fisheries, Bulletin of the Ceylon Fisheries, vol. 3, December 1929). It includes a review of the scientific investigations since 1902 and is directly concerned with the industrial problems and those of economic importance.

The outstanding features of the Ceylon pearl fisheries are their irregularity and uncertainty. After the fishery of 1891, there was a barren interval of eleven years followed by five splendid fisheries in 1903–7, and after 1907 there was an interval of seventeen bad years before the fishery of 1925; making only six fisheries since 1891—a period of thirty-four years.

The establishment of a Department of Fisheries, with the appointment of a marine biologist, provision of a modern steam trawler, and the regular inspection of the pearl banks, have made possible a survey of the littoral waters of Ceylon, and much is now known of the biology of the coastal waters in general and of the pearl-banks in particular. The investigations carried on since the War have been restricted to the inspections, supplemented by trawling and dredging operations and to periodic hydrographical cruises in the Gulf of Mannar.

The situation of the pearl-banks area, with its hundreds of square miles of deep water, its lack of protection from the violence of the south-west monsoon, and a complete lack of a suitable situation in which to establish a 'nursery', makes cultural work

a matter of extreme difficulty if not impossibility. Mortality of the oysters is enormous, both young and old. At no stage in its life history is the oyster immune from attacks of predaceous fishes, especially rays, and from the effects of silting sand or other vicissitudes, including accumulating growths of *Sargassum* weed. Any system of cultivation and protection must deal with half-grown and full-grown oysters. Such a programme of oyster culture is apparently not practicable in Ceylon because local conditions are unfavourable and because the cost of such a scheme, even if feasible, would be prohibitive.

The question as to how the banks became repopulated after a term of blank years is still a matter of uncertainty. At one time it was thought that the spat from the Tuticorin banks was wafted, under favourable conditions, to the Ceylon side and vice versa, there being two breeding seasons in the year, one at the height of each monsoon, July–August and December–January, and this is probably one cause of repopulation. Other causes, however, may be important, such as repopulation from a few scattered oysters or from adjacent beds in the same local area. As to the complete disappearance of oysters after they have established themselves in large numbers, the main reason seems to lie in the geographical peculiarities of the Ceylon pearl banks. Both the Ceylon and Tuticorin banks lie on a submerged shelf limited in extent and varying from 5 fathoms to 12 fathoms in depth, which drops suddenly into one hundred fathoms. The pearl banks never lie more than five miles from the 'overfalls' to the west and the same distance from the shallows to the east. The floating larvæ are at the mercy of the elements. They might easily be carried out into deep water or shoreward into too shallow water. Then the irregular currents would cause the irregularity of the oysters, and although there are two spawning seasons and oysters are sexually mature at twelve months, there is no guarantee that a bed of oysters, once established, will produce a spat-fall on the banks.

The memoir includes chapters on the methods of pearl fishing, the history of the oysters fished in 1925, the age and growth of the oysters, and nautical notes.

University and Educational Intelligence.

ABERDEEN.—The King has been pleased, on the recommendation of the Secretary of State for Scotland, to approve the following appointments: Dr. James Ritchie, presently Keeper of the Natural History Department of the Royal Scottish Museum, Edinburgh, to be Regius professor of natural history in succession to Prof. J. Arthur Thomson, on whom a knighthood was conferred in the King's birthday honours list; Dr. David Campbell, Pollok lecturer in pharmacology and therapeutics in the University of Glasgow, to be Regius professor of materia medica in succession to Prof. C. R. Marshall.

CARDIFF. Dr. R. T. Dunbar, lecturer in physics, has been appointed to the chair of physics at the University College of South Wales and Monmouthshire, in succession to Prof. H. R. Robinson, who has been appointed professor of physics at East London College (University of London).

GLASGOW.—The King, on the recommendation of the Secretary of State for Scotland, has approved the appointment of Dr. John Walton, lecturer in botany in the University of Manchester, to be Regius professor of botany in the University of Glasgow in succession to Prof. J. M. F. Drummond, whose resignation takes effect on Sept. 30.

THE issue of the *British Medical Journal* for Aug. 23 contains an account of medical teaching in Burma and of the new medical college opened at Rangoon last October. Until the beginning of the present century, Rangoon was very backward as regards public buildings and particularly hospitals and schools, which were out-of-date. Since then, however, as the result of a government grant and the generosity of numerous private donors, a remarkably rapid improvement has taken place. Rangoon, which has a population of nearly 400,000 inhabitants, now possesses a general hospital of 650 beds, a hospital for women, and a mental hospital, all of the most modern type and equipped with up-to-date clinical and postmortem theatres. The new college of medicine building, for the equipment and design of which Lieut.-Col. T. F. Owens, the dean of medical studies, and Mr. S. P. Bush, the consulting architect, are responsible, is described as being unsurpassed by any teaching institute in Asia. It contains departments for physiology (including histology and biochemistry), anatomy, forensic medicine, operation surgery, pharmacology and materia medica, and pathology and bacteriology, with amply stocked and well arranged museums attached to the departments of pathology and forensic medicine, a library, and a large lecture theatre. Instruction in hygiene is given at the recently opened Institute of Hygiene, of which the director is the University lecturer in hygiene. Seven University medical chairs have been established—for anatomy, physiology, pathology, forensic medicine, surgery, medicine, and obstetrics respectively. All the heads of these departments are Europeans, as is also the case in the departments of arts, science, engineering, and law.

A CO-OPERATIVE large-scale study of the relations of secondary and higher education in the State of Pennsylvania is now in progress under the direction of the Carnegie Foundation for the Advancement of Teaching and the Educational Commission of the State. It represents an attack on the problem how to transform mass education into particular education, aiming at the maximum development and integration of each individual pupil's capacities for achievement and self-direction. Begun a year ago and planned to be completed in six years, the inquiry is being conducted, not by an outside staff but by the institutions (some fifty in number) themselves. An interim account of it appears in this year's annual report of the Foundation. At present attention is focused on the 'wastage' involved in the entry upon a four-years' college course in the institutions under observation of more than a thousand students annually who drop out during or at the conclusion of the first semester, and the still larger number who drop out during the remainder of their first year. To what extent is this wastage attributable to the high school's misjudgment of the fitness of its pupils for a university course, and to the college's failure to guide, inspire, and confirm its freshmen? To answer this question, procedures have been devised for placing at the disposal of the high school sufficient data covering a considerable period of school life for truly estimating the pupil's equipment of genuinely assimilated knowledge and state of mind before recommending entry into college, and for enabling the college to discharge its "first duty with the new student": "to assure itself of an intelligent, sincere, and feasible purpose within him and to make certain that he is so situated that this purpose can be fulfilled".

Historic Natural Events.

Aug. 31, 1886. Charleston Earthquake.—This visited a district in which earthquakes were previously almost unknown. Though not destructive in the ordinary sense, its disturbed area (of 2¾ million square miles) has seldom been exceeded. The earthquake originated in two foci about 13 miles apart and situated at depths of about 12 and 8 miles. The velocity of the earth-waves was 5·2 km. per sec.

Sept. 1, 1667. Hurricane at St. Kitts.—M. Laurent, the Governor of St. Kitts (then French), wrote in a letter: "There has blown here the most violent hurricane ever known, and I hold myself obliged to inform you that this island is in the most deplorable state that can be imagined and that the inhabitants could not have suffered a greater loss, or been more unfortunate, except they had been taken by the English."

Sept. 1, 1859. Solar Disturbance and Magnetic Storms.—During the period Aug. 28–Sept. 7, magnetic disturbances, accompanied by remarkable auroral displays, took place throughout the world. There were two major storms, the first commencing on Aug. 28 and the second on Sept. 2; it was found that each began suddenly, at (or nearly so) the same absolute time throughout the globe, and each corresponded in time with a great auroral display. Superimposed upon the disturbed conditions between these major storms, there was a moderate but marked disturbance with a sudden commencement at $11^h\ 20^m$ G.M.T. on Sept. 1. At the same time, two solar observers, Carrington and Hodgson, observed independently a brilliant patch of light that lasted about 5 min. ($11^h\ 18^m$–$11^h\ 23^m$) and moved some 35,000 miles across an unusually large and complex sunspot then nearly in line with the earth. The coincidence between the occurrence of this solar outburst (unique in observations made with direct telescopic means without the discerning power of the spectroscope applied more recently) and the minor magnetic storm was thought, at that time, to be significant. (A time interval of about 24 hours between some form of solar disturbance and the commencement of an associated terrestrial magnetic storm is now recognised.)

Sept. 1-3, 1883. Great Storm.—This storm was traced from the tropical Atlantic, where it appeared as a violent hurricane on Aug. 25, along the coast of North America and across the Atlantic to the British Isles. In mid-Atlantic the barometer fell below 957 mb. (28·25 in.). The storm reached England on the afternoon of Sept. 1, and the centre crossed England in a north-easterly direction from Pembroke to Berwick. There was a violent gale over western and southern England, as well as France and Germany, accompanied by very heavy rain. In the Thames one of the lowest tides on record occurred on Sept. 2.

Sept. 1, 1923. Disastrous Earthquake in Japan.—The Kwanto earthquake of 1923, though not the strongest, was the most destructive of all Japanese earthquakes, owing to the great fires that followed the shock. The burned-out districts in Tokyo and Yokohama covered about 6·9 and 3·1 square miles, or nearly half the area of each city; 99,331 persons were killed, 103,733 wounded, and 43,476 missing, while the number of houses completely ruined exceeded half a million, and the value of property destroyed was about 550 million pounds. The epicentre lay in Sagami Bay, to the north of the island of Oshima. The earthquake was accompanied or followed by remarkable distortions of the crust. Though the greatest known elevation on land was 7 ft. 8 in. and the greatest subsidence 5 ft. 4 in., the changes in the bed of Sagami Bay were on a scale hitherto unknown. The total areas elevated and depressed were 90 and 270 square miles, and the total volumes 5 and 12 cubic miles, the greatest uplift being 755 ft. and the greatest subsidence 1312 ft. The earthquake seems to have been caused by block movements of the crust, especially along the continuation of the rift-valley of the Sakawa River.

Sept. 1-3, 1923. Cumulus Clouds over Tokyo.—Following the destructive earthquake in Tokyo on Sept. 1, great fires broke out and continued for about 40 hours. Yokohama and other towns were also burnt. The heat of the fires caused rapid ascent of air and a strong indraught, the wind velocity reaching gale force. Gigantic cumulus clouds developed above the fires in consequence of this uprush of air, the tops of the clouds being five miles above the ground. Whirlwinds were formed over the fiercest fires, and it was observed that when these fires decayed the whirls moved on to other fires.

Sept. 2-3, 1588. Armada Gales.—It has frequently been stated that the defeat of the Spanish Armada in 1588 was largely due to storms. Careful historical investigation has shown, however, that the weather was not especially bad until the remnant of the fleet was in the open Atlantic west of Scotland and Ireland, when a severe gale occurred on Sept. 2-3, which drove some of the ships on to the coast of Ireland. Bad weather was also reported by the English fleet in the Downs.

Sept. 2, 1666. Drought before Great Fire of London.—On this date Pepys recorded: "The wind mighty high and driving it [the fire] into the City; and everything, after so long a drought, proving combustible . . . the wind carries it into the city. [The fire] still increasing, and the wind great, it being brave dry, and moonshine, and warm weather." The general wind direction during the fire was easterly, for an entry on Feb. 3, 1667, records that pieces of burnt paper were carried by the wind so far as Cranborne, near Windsor. The drought continued until Sept. 9.

Sept. 3, 1919. Detonating Meteor.—At 10.25 P.M. a meteor appeared over north-west Germany at a height which was afterwards calculated as 76 miles. It traversed a path of 194 miles from south-south-east to north-north-west in less than six seconds, and disappeared at a height of about 17 miles over Schleswig-Holstein. Its brightness was such that it was visible at a distance of more than 300 miles. Nearer the path its apparent diameter was given as up to twice that of the full moon and it made the night as light as day. From the reports received, the diameter of the glowing sphere was calculated by A. Köppen as about 270 metres (890 feet).

Sept. 3, 1925. *Shenandoah* Squall.—The United States airship *Shenandoah*, while flying over south-eastern Ohio, was struck by a violent squall with powerful vertical air-currents. The airship broke in two, and out of 43 officers and men 14, including the commander, were killed.

Sept. 6, 1926. Detonating Meteor.—About 9.50 P.M. a brilliant meteor travelled from the North Sea near Bridlington over Sheffield at a speed of 19 miles a second. It gave a brilliant greenish light, and was followed by a reddish trail, and the illumination was seen over almost the whole of the British Isles, as well as in Belgium and France. Just beyond Sheffield it burst with a rumbling like thunder or heavy explosions, which at Sheffield lasted for 43 seconds. An interesting feature was that while the explosion was distinctly heard at distances of 70-140 miles, and at one place 100 miles distant houses were shaken, at intervening places no noise was heard, thus providing a good example of an outer zone of audibility.

Societies and Academies.

PARIS.

Academy of Sciences. July 7.—The president announced the death of Georges Neumann, *correspondant* for the Section of Rural Economy.—**H. Deslandres**: The properties of the lines and abnormal series in atomic spectra.—**Charles Richet**: A paradox on (visual) accommodation. Looking down an avenue, after fixing the eyes on the nearest trees, there is an obvious effort of accommodation when bringing a more distant tree into focus. In a picture showing the same view in perspective, there is still a distinct effort of accommodation in changing from the nearer to the more distant trees. This is a paradox, since all the objects are in the same plane.—**Louis Roy**: The dynamical adiabatic law relating to elastic surfaces.—**N. St. Georgesco**: A problem of the calculus of probabilities with application to the search for unknown periods of a cyclic phenomenon.—**Henri Poncin**: The flow in a canal.—**J. Baurand**: The formation of waves at the surfaces of liquids.—**G. W. Ritchey**: First results in celestial photography obtained with the Ritchey-Chrétien telescope.—**Alex. Véronnet**: The trans-Neptunian planet. The determination of an orbit by three observations.—**Al. Proca**: Dirac's equation. The sixteen ψ_k components.—**E. Sevin**: The origins of a synthesis of the laws of the physical world.—**E. Kogbetliantz**: The velocity of propagation of gravitation.—**André Marcelin** and **Mlle. Simone Boudin**: Coloured stratifications by sublimation. **Mlle. Suzanne Husson**: The mechanical action exerted in a conductor by electromagnetic waves. An expression for the force due to the electromagnetic radiation on a single element oscillating in resonance has been calculated, and an apparatus has been designed and constructed capable of detecting this force.—**S. Holgersson** and **Mlle. A. Serres**: The properties and crystalline network of the ferrites. The magnetic properties of zinc ferrite differ entirely from those of the ferrites of magnesium, lead, copper and nickel. Since X-ray study proves that all these compounds have the same crystalline structure, one possible explanation of this anomaly fails. It is concluded that the magnetic properties of Fe‴ depend on the nature of the other atoms placed at the nodes of the network near those which are occupied by Fe‴.—**G. Bruhat** and **J. Terrien**: The ultra-violet absorption of solutions of tartaric acid: the influence of concentration. The absorption of tartaric acid solutions for concentrations between 0·16 and 3·3 gm.-mols per litre obeys Beer's law exactly. This confirms the conclusion drawn from the study of the rotatory dispersion, that there is nothing pointing to the existence of two forms of the tartaric acid molecule possessing different absorptions.—**Marcel Dufour**: The orthogonal trajectories of the generators of a ruled surface.—**Ch. Guilbert** and **Livet**: An improved method for taking stereoradiographs.—**Chapas**: The form of the solubility curve of benzoic acid in toluene. Taking as co-ordinates the reciprocal of the absolute temperature and the logarithm of the concentration, the curve found by experiment is a straight line which passes through the melting point of benzoic acid, (t = 121·9, c = 100 per cent).—**O. Liévin** and **J. Declerck**: The kinetics of alkaline solutions of iodine. The case of alkaline borates.—**Léon Thiéry**: The influence of nickel and chromium on the properties of malleable cast iron. Nickel can replace silicon from the point of view of the graphitisation effect: it allows the temperature of graphite formation to be lowered and gives a finer grained and better disseminated graphite. Chromium has the opposite effect; it hinders graphitisation, increases the hardness, and reduces elongation and resilience.—**Claude Fromageot**: The action of ultra-violet light on dimethylpyruvic acid. Dimethylpyruvic acid, in neutral or alkaline aqueous solution, under the influence of ultra-violet light, forms a compound capable of setting free iodine from potassium iodide. This property is connected with an ethylene linkage.—**Mlle. J. Foret**: Calcium nitroaluminate. A description and the preparation and properties of the double salt $3CaO . Al_2O_3 . Ca(NO_3)_2 . 16 H_2O$.—**Pierre Poulenc**: Complex compounds of rhodium bromide and pyridine.—**Charles Boulanger**: The reduction of metallic salts in solution by aluminium.—**P. Delauney**: The biochemical synthesis of β . 5-iodosalicylglucoside.—**Pereira de Sousa**: The eruptive rocks of the western part of Algarve, Portugal.—**Jean Lugeon**: The radioelectric determination of the position of sand storms in the Sahara from a great distance.—**R. Bureau**: The study of the propagation of electric waves with the aid of atmospherics.—**A. Gruvel**: Some submarine springs observed on the Libano-Syrian coasts.—**René Girard** and **Robert Lemesle**: Polystely in *Ramondia pyrenaica*.—**Antonin Némec, Joseph Lanik**, and **Mme. Anna Koppovà**: A colorimetric method for rapidly determining the citric acid soluble phosphoric acid of the soil.—**D. Bennati, J. Gautrelet**, and **E. Herzfeld**: Adrenaline, the alkaline reserve and apnœa.—**Georges Bourguignon** and **Mlle. Marie Louise Verrier**: The mechanism of (visual) accommodation in the Teleosteans.—**Paul Mathias**: The evolutive cycle of a trematod of the family of the Notocotylidæ (*Notocotylus attenuatus*).—**Marcel Avel**: The rôle of the nervous system in the regeneration of the head in *Lumbricus*.—**M. Lemoigne** and **P. Monguillon**: The presence of acetylmethylcarbinol and of 2·3 butylene glycol in the blood of the higher animals.—**G. Guittonneau, H. Delaval**, and **Mlle. M. Bejambes**: A lactic fermentation of certain sugars at a temperature of 70° C.

Diary of Societies.

CONGRESSES.

SEPTEMBER 1 TO 6.

INTERNATIONAL AIR CONGRESS (at the Hague).—Sections: Aerial Traffic, Science and Technics, Legal Questions, Medical Questions, and Aerial Tourism.

SEPTEMBER 3 TO 10.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Bristol).

Wednesday, Sept. 3, at 8.30 P.M. (in Colston Hall).—Prof. F. O. Bower: Size and Form in Plants (Presidential Address).

Thursday, Sept. 4, at 10 A.M.—(A) Discussion on The Meteorological Relations of Atmospherics.
(A) E. H. Linfoot: A Problem in the Analytic Theory of Numbers.
(B) Prof. G. T. Morgan: A State Experiment in Chemical Research (Presidential Address).
(C) Prof. S. H. Reynolds, J. W. Tutcher, and Prof. L. S. Palmer: The Geology of the Bristol Area.
(D) Dr. W. T. Calman: The Taxonomic Outlook in Zoology (Presidential Address).
(E) W. W. Jervis: General Introductory Survey of the Bristol Region
(F) G. Ponsonby: The Incidence of the Cost of Road Maintenance and Construction.
(G) T. F. Hurley and R. Cook: The Influence of Turbulence upon Highest Useful Compression Ratio in Petrol Engines.
(H) Dr. H. S. Harrison: Evolution in Material Culture (Presidential Address).
(I) Prof. H. S. Raper: The Synthetic Activities of the Cell (Presidential Address).
(J) Discussion on The Psychology of Adolescence.
(K) Dr. A. W. Hill: Recent Developments and Present-day Problems in Taxonomic and Economic Botany (Presidential Address).
(L) Miss Margaret Drummond, Dr. J. A. Hadfield, and Dr. W. E. Blatz: The Pre-School Child.
(M) Discussion on The Influence of Fertilisers on the Yield and Composition of Plants.
At 10.15 A.M.—(K) D. W. Young: Cultivation of Hardwoods.
At 10.20 A.M.—(A) Dr. L. S. Bosanquet: The Summability of Fourier Series.

At 10.40 A.M.—(G) C. F. Abell: Some Recent Progress in Air-cooled Aero-Engine Development.
(A) Prof. E. C. Titchmarsh: Functions which are their own Fourier Transforms.
At 10.45 A.M.—(E) Mrs. D. Portway Dobson: The Bristol District in the Prehistoric Period.
At 11 A.M.—(D) Miss S. M. Manton: *Anaspides* and *Paranaspides*.
(F) Discussion on The Value and Limitation of Costing in Industry and Agriculture.
(K) A. Howard: Our British-Grown Hardwood Trees and Timbers.
At 11.10 A.M.—(K) Dr. W. B. Turrill and E. M. Marsden-Jones: Species Studies in Plants.
At 11.15 A.M.—(C) E. H. Davison: The Granite of Western Cornwall, its Alteration and Contact Metamorphism.
(H) Discussion on A Proposed National Folk Museum.
At 11.20 A.M.—(G) Dr. S. J. Davies and E. Giffen: The Present Position of the High-Speed Heavy-Oil Engine.
At 11.30 A.M.—(A) Prof. M. Siegbahn: The Highly Ionised Spectra in the Extreme Ultra-Violet.
(A) T. W. Chaundy: A Note on the Hypergeometric Equation.
(D) Prof. H. G. Cannon: (*a*) On the Internal Anatomy of a Marine Ostracod, *Cypridina* (*Doloria*) *levis Skogsberg*. (*b*) An Undamaged Specimen of *Nebaliopsis typica* G.O. Sars.
(E) S. J. Jones: The Historical Geography of Bristol.
(I) Prof. A. F. S. Kent: Some Unpublished Work on the Heart.
At 11.40 A.M.—(C) Dr. G. Slater: The Glaciated Rock-surfaces of Nooitgedacht, and the Upper Dwyka Boulder-shales of Griqualand West.
At 11.45 A.M.—(K) W. H. Guillebaud: Experimental Studies on the Artificial Regeneration of Oak.
At 11.50 A.M.—(A) Dr. D. M. Wrinch: Recurrence Relations and some Definite Integrals involving Legendre Polynomials.
(B) Prof. F. E. Francis, Dr. T. Malkin, and S. H. Piper: Natural Fatty Acids.
(K) Prof. F. A. F. C. Went: Wegener's Theory and the Distribution of the Podostemaceæ.
At 12 noon.—(A) W. Sucksmith: The Gyromagnetic Effect in Paramagnetic Substances.
(K) Prof. R. S. Adamson: Annual Rings in a Monocotyledon.
(L) Rt. Hon. Lord Eustace Percy: A Policy of Higher Education (Presidential Address).
At 12.10.—(A) Miss R. C. Young: The Algebra of Infinities.
(B) Dr. M. Nierenstein: Pyryllium Series.
(C) Prof. J. W. Gregory: The Recent Cable Fractures in the Western Atlantic.
At 12.15.—(D) Prof. F. A. E. Crew: The Effects of Density on a Mouse Population.
(I) Dr. F. W. Edridge-Green: Pseudo-Isochromatism and the Detection of Colour-Blindness.
At 12.30.—(A) Prof. W. E. H. Berwick: The Complex Multiplication of Elliptic Functions.
(B) Dr. H. T. S. Britton, Dr. R. A. Robinson, and W. L. German: Complex Acids of the Rarer Elements.
(C) S. H. Straw: On the Fauna of the Palæozoic Rocks of the Little Missenden Boring.
At 2.—Conference of Delegates of Corresponding Societies.
Prof. P. Abercrombie: National Parks (Presidential Address).
(I) R. J. Bartlett: Some Effects of Low Frequency Vibration on Body and Mind.
At 2.15.—(D) The Work of the Great Barrier Reef Expedition:—A. P. Orr: Conditions in the Sea-water bathing Coral Reefs.
At 2.30.—(H) Mrs. D. P. Dobson: General Survey of pre-Roman Sites in the Bristol District.
Prof. D. H. Campbell: The Preservation of the Red Wood Forests in the Western States.
(K) J. Macdonald: The Measurement of Standing Trees.
(M) T. Wallace: Soil Surveys.
At 2.40.—(J) E. Farmer: A Consideration of the Frequency Distribution of Certain Tests.
At 2.45.—(D) F. S. Russell and Miss S. M. Marshall: The Plankton of the Seas round the Great Barrier Reef.
At 2.50.—(M) T. Swarbrick: Stock and Scion Relationship.
At 3.—Miss G. V. Barnard, Dr. Cyril Fox, and Dr. M. Wheeler: Folk Museums and Local Societies.
At 3.10.—(M) F. Tutin: Investigations on Tar Distillate Washes.
At 3.15.—(D) Dr. C. M. Yonge: The Food, Feeding, and Digestive Processes of Corals.
At 3.20.—(J) H. E. O. James: Interference.
At 3.30.—(H) Dr. R. E. M. Wheeler: A Prehistoric, Roman, and Post-Roman Site in Gloucestershire; the Excavations at Lydney.
(K) Dr. R. N. Chrystal and E. R. Skinner: (*a*) Notes on the Biology of *Xylonomus brachylabris*. (*b*) Notes on the Biology of *Xyphidria prolongata* . . .
(M) A. W. Ling: Sugar Beet Investigations.
At 3.45.—Sir Leonard Hill: The Registration of Ultra-Violet Light in Towns and Country.
(D) Dr. T. A. Stephenson: The Growth, Breeding, and Life Conditions of Corals.
At 3.50.—(M) C. V. Dawe: The Work in Agricultural Economics at Bristol University.
At 4.—(H) R. W. M. Wright: Celtic and Saxon Bath.
(J) Mr. Sahai: Outstanding Features of the Circular Type of Character.
At 4.10.—(M) F. Hirst: Problems in connexion with the Establishment of the Canning Industry.
At 4.30.—(H) Mrs. E. Clifford: Report on the Barnwood Discoveries.
At 5.15 (at Merchant Venturers' Technical College).—Sir Daniel Hall: Apples: the Bearing of Research on Improved Production (Public Lecture).

Friday, Sept. 5, at 10 A.M.—(A) Papers dealing with Aspects of the Solid State by Prof. J. E. Lennard-Jones, Prof. W. L. Bragg, and Dr. E. Bloch.
(B) Discussion on The Present Position of the British Dyestuff Industry.
(C) Discussion on The Validity of the Permian as a System.
(D) Dr. D. de Lange: The Phylogeny of the Placenta.
(E) Prof. P. M. Roxby: The Scope and Aims of Human Geography (Presidential Address).
(F) Sir John Mann: Some Neglected Aspects of the Housing Problem. Sir Josiah Stamp: The Inheritance Enquiry.
(G) Sir Ernest W. Moir, Bart.: The Interdependence of Science and Engineering, with some Examples (Presidential Address).
(H) Miss D. A. E. Garrod: Excavations in the Caves of the Wady el-Mughara.
(J) Mrs. S. Isaacs: The Relation between Thought and Fantasy in Young Children.
(K and M) Discussion on Mineral Elements in Plant Nutrition.
(L) The Curricula of Central Modern and Senior Schools.
At 10.30 A.M.—(D) Dr. C. Tate Regan: The Evolution of the Primates.
(I) Prof. R. R. Gates: The Blood Groups and their Inheritance.
At 10.35 A.M.—(A) Dr. R. A. Fisher: Inverse Probability.
(A) Dr. J. Henderson: The Methods of Construction of the Earliest Tables of Logarithms.
At 10.45 A.M.—(H) G. Horsfield: First Excavations at Petra.
At 11 A.M.—(E) Town Planning.
(G, I) Discussion on Air Pressure Variations encountered in Engineering Works and their Physiological Effects.
(I) Miss M. Grace Eggleton and Prof. C. Lovatt Evans: The Removal of Lactic Acid after Exercise in the Mammal.
(J) Prof. C. W. Valentine: The Foundations of Child Psychology (Presidential Address).
At 11.15 A.M.—(H) Sir Flinders Petrie and E. Macdonald: Neolithic and Palæolithic in the Beersheba Basin.
At 11.30 A.M.—(A) Dr. J. Wishart: Combinatorial Methods in Problem of Sampling.
(D) Prof. F. H. Edgeworth: On the Musculature for opening and closing the Mouth in Vertebrates.
At 12 noon.—(A) J. O. Irwin: The Approximate Evaluation of Single and Double Integrals.
(D) Miss D. M. Sladden: (*a*) The Adaptation of *Alytes* to Warmth. (*b*) The Production of Defects in the Frog.
(H) R. F. Parry: Cheddar Excavations.
(K) A. Malins Smith: The Composition of Upland Bog Water and its Relation to Algal Vegetation.
(M) Dr. J. F. Tocher: The Adulteration of Milk with Water.
At 12.30.—(A) Dr. L. J. Comrie: Modern Babbage Machines.
(D) Prof. J. Graham Kerr: John Samuel Budgett, a Bristol Naturalist.
(H) Dr. H. Taylor: Recent Work of the Spelæological Society.
At 2.15.—(D) H. W. Miles: On the Diversity of Habit of three Saw-flies (*Tenthredinæ*) infesting Gooseberry.
At 2.30.—(E) Col. E. W. Lennard: Some Intimate Bristol Connexions with the Overseas Empire.
(H) Sir Flinders Petrie: Excavations at Bethpelet, Palestine.
(M) Sir Frederick Keeble: Agricultural Problems in South Africa.
At 2.40.—(J) Miss C. A. Simmins: The Mental Processes involved in learning a Foreign Language.
At 2.45.—(D) Miss M. J. Norris: The Factors affecting Fertility in certain Moths.
At 3.—(M) Commissioner D. C. Lamb: The "Human Aspect" in relation to Agriculture.
At 3.15.—(D) Prof. J. W. Munro: The Feeding Habits of Bark Beetles.
(E) Major R. W. G. Hingston: British Guiana.
(H) H. St. George Gray: Explorations of Somerset Earthworks.
At 3.20.—(J) H. Binns: Some Experiments with Wool-textile Trade Advertisements.
At 3.30.—(M) H. W. Miles: Recent Research in the Potato Root Eelworm and its Relation to Potato Sickness.
At 3.45.—(D) J. V. Pearman: The Natural History of the *Psocoptera*.
At 4.—(H) C. W. Phillips: The Circle, Avenue, and other Earthworks on Walton Down, near Clevedon.
(J) Dr. C. S. Myers: The Place of Industrial Psychology in a University City.
At 5.15—Sir Arthur Keith: What Dr. John Beddoe did for Modern Anthropology (Public Memorial Lecture).
At 8 (in Victoria Rooms).—Prof. E. V. Appleton: Wireless Echoes (Evening Discourse).

Monday, Sept. 8, at 10 A.M.—(A) Dr. F. E. Smith: The Theories of Terrestrial Magnetism (Presidential Address).
(B) Discussion on Chemotherapy.
(C) Prof. O. T. Jones: Some Episodes in the Geological History of the Bristol Channel Region (Presidential Address).
(D) C. B. Williams: Migration among the Lepidoptera.
(F) Prof. P. S. Florence: The Theory of Women's Wages.
(G) The Trend of Airship Construction:—Lt.-Col. V. C. Richmond: The Development of Rigid Airship Construction.—B. N. Wallis: The Design and Construction of H.M.A. *R100*.—W. E. Doerr: The Airship *Graf Zeppelin*.
(H) L. S. B. Leakey: The Kikuyu.
(I, J) Discussion on In what Sense can we speak of Primary Colours?
(K) Prof. W. Goodspeed: Cytogenetic Evidence as to Species Origins and Relationships in the Genus *Nicotiana*.
(K) Capt. C. R. Robbins: Air Surveys in Relation to Forestry.
(M) Dr. P. J. du Toit: Veterinary Science and Agriculture (Presidential Address).
At 10.15 A.M.—(E) S. K. J. Baker: The Population Map of Uganda: A Geographical Interpretation.
At 10.30 A.M.—(L) Disciplinary Values in Education.
At 10.40 A.M.—(K) M. Thomas: Fermentations in the Cells of Higher Plants in the Presence of Oxygen.
At 10.45 A.M.—(D) N. N. Murti: The Physiology of the Heart of Larval Starfish and Sea-Urchins.
(H) A. L. Armstrong: The Antiquity of Man in South Africa, as demonstrated at the Victoria Falls, Rhodesia.

At 11 A.M.—(A) Dr. P. A. M. Dirac: The Proton.
(C) Prof. A. H. Cox and D. A. B. Davies: On a 100-feet Base-level in the Cardiff Area.
(E) M. Amer: The Social Geography of the Egyptian Oases.
(K) W. L. Taylor: The Afforestable Lands of Great Britain.
At 11.10 A.M.—(K) Prof. D. Thoday and N. Woodhead: The Growth and Metabolism of *Kleinia articulata*.
At 11.15 A.M.—(C) Prof. G. Delépine: The Dinantian Zones of Goniatites in the North of France and Belgium.
(D) W. E. Swinton: The Plesiosaurs of the Bristol Museum.
At 11.30 A.M.—(A) Prof. A. C. Dixon: Integral Equations.
(F) Prof. T. E. Gregory: Rationalisation and Technological Unemployment (Presidential Address).
(H) Miss M. A. Murray: Excavations in Minorca.
(I) A. D. Macdonald and J. Schlapp: Quantitative Aspects of the Action of Drugs.
(J) Dr. R. H. Thouless: (*a*) The Influence of the Physical Object on Perception, and its Bearing on the Laws of Perspective. (*b*) Dr. Houston's Substitute for Weber's Law.
At 11.40 A.M.—(K) H. Evans: Buffering and Acidity in *Kleinia articulata*.
At 11.45 A.M.—(G) Dr. A. E. Trueman: The Classification of the Upper Carboniferous.
(D) M. A. C. Hinton: Extinct Cave Fauna of the Bristol District.
(E) W. Fogg: Morocco: Some Aspects of the Sebou Basin.
At 12 noon.—(C) Dr. D. A. Wray and Dr. A. E. Trueman: The Sequence of Non-Marine Lamellibranchs in the Upper Carboniferous of Yorkshire.
(C) Dr. D. A. Wray: The Succession of Marine Bands in the Coal-Measures of Yorkshire.
(L) Miss L. E. Hawker: A Quantitative Study of the Geotropism of certain Seedlings, with Special Reference to the Nature and Development of their Statolith Apparatus.
(K) Dr. J. Burtt Davy: A Preliminary Report on a Recent Investigation of the Forest Floras of Northern Rhodesia, Nyasaland, Pemba, and Zanzibar.
At 12.10.—(A) R. Stoneley: The Identification of the Phases of Earthquake Shocks.

Science and Leadership.

AMONG the changes which the British Association for the Advancement of Science has witnessed since its formation in 1831 is the gradual disappearance of the demarcation between science and industry. As Lord Melchett pointed out in a recent address, the endeavour to distinguish between pure and applied science has now lost any kind of meaning. No clear distinction is possible between science and industry. The results of research work of the most speculative character often lead to outstanding practical results. Such progressive firms as Imperial Chemical Industries, Ltd., now follow in Great Britain the practice long current in Germany by fostering close contact with the scientific research work of the universities.

The relation of science to industry was a main theme at the discussions of the British Association at Cape Town and Johannesburg last year, and this year's programme affords further evidence of the interpenetration of science and industry. The discussions on the influence of fertilisers on the yield and composition of plants, on chemotherapy, and on the present position of the British dyestuffs industry, and the addresses to be given on recent progress in air-cooled aeroplane development, on investigations on tar distillate washes, on sugar beet investigations, the bearing of research on improved production of apples, Dr. P. I. du Toit's presidential address on veterinary science and agriculture, and Sir Ernest W. Moir's presidential address on the interdependence of science and engineering, are sufficient evidence that the outlook of modern science is essentially practical and related to the requirements of industry. On the other hand, scientific leadership is now a characteristic of all progressive and prosperous branches of industry. The industries in which the neglect of science has been most marked are those which are most stagnant or most acutely confronted by problems of reconstruction.

If, however, it is true that in the last twenty-five years, science has rapidly assumed the responsibility of leadership in industry, a yet wider responsibility is now demanded of it. Under the conditions of modern civilisation the community in general, as well as industry, is dependent upon pure and applied science for its continued progress and prosperity. Under the influence of modern scientific discoveries and their applications, not only in industry but also in many other directions, the whole basis of society is rapidly becoming scientific, and to an increasing extent the problems which

confront the national administrator, whether judiciary or executive, involve factors which require scientific knowledge for their solution. The road traffic problem of to-day, for example, can be traced directly to the enormous expansion in output of motor-cars, and therefore reduction in costs of production, which resulted from chemical research in the field of lacquer solvents. The introduction of oil-fuel for steamers immediately created a problem of waste-fuel disposal, and the layman could not be expected to predict the serious consequences at many of our coastal resorts of the short-sighted policy of dumping waste-oil at sea.

Problems of atmospheric or riparian pollution are all largely problems which have arisen through society using the results of scientific discoveries and their applications, unguided by scientific and unprejudiced investigation of their reactions on the life of the community. Many such problems need not have become acute had an elementary amount of such foresight and scientific investigation been exercised in the early stages of the development of scientific inventions before vested interests had been created.

It is never easy to envisage the full consequences of a scientific discovery, but it is an imperative need of to-day that scientific workers should attempt to predict the consequences of their discoveries and to suggest means of dealing with the probable situation at the earliest and easiest moment. Much useless expenditure of public money, and many unsatisfactory and makeshift arrangements, might easily have been avoided in the past had scientific workers of sufficient foresight and character taken their share in local and national administration. Again, the control of public expenditure on, for example, the National Physical Laboratory or the Chemical Research Laboratory at Teddington in the final issue must be determined by scientific or technical knowledge, and cannot be regarded as satisfactorily exercised by administrators who are dependent on the advice of others for that knowledge.

In recent years the rapid growth in the rate of all kinds of international communication and transport has forced on industry an outlook and organisation that to an astonishing extent are international. These same forces have, however, enlarged the bounds within which mistaken policies can exert their ill-effects. Recent historical research has demonstrated that the difficult racial problems confronting the Union of South Africa to-day are the result of mistaken policies determined by political prejudices three generations ago. In the modern world the dangers arising from mistakes caused by prejudice and neglect of impartial or scientific inquiry are infinitely more serious. In an age when nearly all the problems of administration and development involve scientific factors, civilisation cannot afford to leave administrative control in the hands of those who have no first-hand knowledge of science.

It would be easy to adduce evidence that, in spite of all the increased interest in scientific research manifested by Parliament, science is far from exerting its fitting influence on government and administration. To the precarious position of the Royal Veterinary College and government indifference to scientific representations thereon we have recently alluded. Dr. A. C. D. Rivett, in an article in the *Times* of Aug. 7, has pointed out how neglect of soil science has been responsible for the economic ruin of many agriculturists and the failure of settlement schemes, and the indisposition to accord to scientific workers effective representation on a number of committees appointed in recent years to deal with a wide range of subjects upon which scientific workers could be expected to speak with authority tells the same tale.

Under modern conditions, therefore, more is required of scientific workers than the mere enlargement of the bounds of knowledge. They can no longer be content to allow others to take the results of their discoveries and use them unguided. Scientific workers must accept responsibility for the control of the forces which have been released by their work. Without their help, efficient administration and a high degree of statesmanship are virtually impossible.

The practical problem of establishing a right relationship between science and politics, between knowledge and power, or more precisely between the scientific worker and the control and administration of the life of the community, is one of the most difficult confronting democracy. The community is, however, entitled to expect from members of the British Association some consideration of such a problem and some guidance as to the means by which science can assume its place of leadership.

There are certain factors involved in the establishment of such a relation which are worthy of mention. In the first place, recent events, notably the tendency of the Civil Service to encroach upon the functions of the judiciary, have demonstrated to many what Mr. and Mrs. Sidney Webb (now Lord and Lady Passfield) observed in 1920: "The great mass of government to-day is the work of an able and honest but secretive bureaucracy, tempered by the ever present apprehension of

the revolt of powerful sectional interests and mitigated by the spasmodic interventions of imperfectly comprehending Ministers." * One essential condition of progress, therefore, is such a modification of the conditions of entry or recruitment and of promotion in the Civil Service that a reasonably adequate appreciation of the value of science is ensured in the whole personnel of the service, and, on the other hand, that avenues of promotion to positions of high administrative responsibility are open to its scientific officers.

The factor of education, however, is of importance not only in the production of a type of administrator more in keeping with the requirements of the modern world, but also in its influence in the production of a more enlightened type of public opinion and one more competent to sort out the issues. In such work of education scientific workers must take a much larger personal part. Much benefit may result from the mere presence of and contact with men of science in numerous committees, councils, and public bodies forming the machinery of local and national administration, and scientific workers must be prepared to offer themselves for election in much larger numbers than they have done hitherto.

The tendency for governments to overlook the need for adequate representation of science on important committees is at least in part due to the failure of scientific workers to indicate the contribution which they are able to make to the subject under discussion. In another sphere it is difficult to believe that the absence of scientific representation from the Melchett-Turner industrial conference has any other explanation than the failure of scientific workers to make a corporate approach.

A restatement of the claims of science to the attention of the civilised world, or the relation of science to social as well as to material progress, is required, and opportunities for scientific workers to participate in such a campaign of education are by no means wanting. Moreover, the recently formed Parliamentary Science Committee has made it considerably easier for scientific workers to demonstrate to Parliament the contribution science makes to the security and progress of the State and the directions in which that contribution can be expanded with advantage to the community.

The extent of the opportunities and the efficacy of such a campaign are largely determined by the representative character and the political strength of the professional organisations of scientific workers. For this reason the development of such organisations during the last decade is full of significance, not only in affording scientific workers wider opportunities of exerting their influence on public life, but also in raising their status to a point that is adequate to discharge the larger functions which the development of society as well as of industry increasingly thrusts upon them.

It is significant that, in contrast to the relative impotence of scientific workers in national affairs, in the international sphere advisory committees of experts have since the War exerted a remarkable and effective influence even when devoid of all legislative authority. To committees of experts organised by the League of Nations, and exercising advisory functions only, is due the credit of the schemes which were successful in rescuing a European State from bankruptcy and chaos and in handling an unemployment scheme which settled a million and a half refugees, following upon the greatest migration in history. These examples sufficiently demonstrate that, given the requisite stimulus and enthusiasm, the scientific expert can already exert an effective influence when normal administrative effort has failed, and when indeed, as in the case of Austria, the problem had been dismissed by statesmen as hopeless.

In truth, scientific workers occupy a privileged position in society as well as industry, and there are welcome signs that this is now recognised by scientific workers themselves. Thus, in his presidential address to the Chemical Society (at Leeds) last year, Prof. Jocelyn Thorpe suggested that the age is at hand in which the changing majorities of governments will no longer be able to determine major policies, except in directions approved by organised industry, and, in advocating the closer organisation of science and industry, stressed the political strength to be obtained thereby. The paper to be read before the British Association on "The Screening of Southend from Gunfire" is further evidence that scientific workers are accepting the responsibility of leadership in matters of social and industrial safety. Whatever inspiration or encouragement the meetings of the British Association may give to scientific workers in the prosecution of their researches, there is no way in which the Association can more fittingly serve humanity than by calling scientific workers to accept those wide responsibilities of leadership in society as well as in industry which their own efforts have made their inevitable lot.

* "A Constitution for the Socialist Commonwealth of Great Britain", 1920, p. 69.

The Roots of Hellenism.

Who were the Greeks? By Prof. John Linton Myres. (Sather Classical Lectures, Vol. 6.) Pp. xxxvii + 634. (Berkeley, Cal.: University of California Press; London: Cambridge University Press, 1930.) 7 dollars.

HOW and through what ethnic migrations and changes were the essentially Mediterranean, almost Oriental, polity, culture, art, and religion of the Ægean Bronze Age transformed into the very different and distinctly European Hellenism in which western civilisation is so largely rooted? This question has confronted all historians since the discoveries of Schliemann and Evans. The answer elaborated by Prof. Myres in 600 closely reasoned pages is the first really serious attempt to co-ordinate into a single whole the bewilderingly diverse data upon which the solution must depend. He gives us for the first time a comprehensive synthesis of the deductions from geography and climatology, from physical anthropology and prehistoric archæology, from comparative philology and religion, from recently discovered Hittite documents and freshly interpreted Egyptian records, and above all, from the now rehabilitated traditional history of the Greeks themselves as embodied in epic, legend, and genealogy.

The combination of these heterogeneous elements to form the solution of our question may be compared to a jig-saw puzzle: the validity of the solution depends upon the coherence of the resultant pattern; and Myres's work passes the test brilliantly. The solver is indeed aided—but also handicapped—by a certain fluidity in some of the elements, due to ambiguities in the archæological record, obscurities in Egyptian and Hittite texts, or confusions in Greek genealogies: here you adjust the element to fit the pattern; and sometimes the element is missing altogether and the lacuna must be filled up with scientific imagination.

None the less, a coherent pattern does emerge, and very seldom is the fit of any element unsatisfactory. Still more rarely has an element been distorted—and that almost exclusively on the margins of the picture: confusions between mounds of many villages like Rustchuk and sepulchral tumuli, an over-high dating for the shaft graves of Mycenæ, inversion of the relations between Ukrainian and Transylvanian and painted wares and between 'Hallstatt' and 'antennæ' swords, or a perhaps too confident acceptation of Forrer's identifications of names in the Hittite texts, in no wise affect the coherence of the central picture.

To summarise in a short review the results of six hundred pages of detailed analysis would be as unjust to the reader as to the author; the discussions of geographical and climatic controls and the ethnographic and historical parallels worked out in digressions that are embarrassing on a first reading are really as essential to the final picture as the central figures which they help to define. It is not the least merit of the book that it takes full account of the complexity of the problem and does not attempt to simplify the picture by the omission of episodes on the pretext that their effects were transitory.

Passing over the more familiar points in the main narrative, we may direct attention to a few conspicuously original features in this genial work. Most striking is the vindication of Greek folk memory as preserved in the Epics and classical authors against the onslaughts of nineteenth century critics and mythographers. Not only does the author demonstrate the internal consistency of the traditions, especially the genealogies, but he also correlates in an entirely novel manner the crises thus disclosed with dated points in the archæological record. Thus in the Argolid the genealogical date for the first king whose name looks obviously personal, and not merely eponymous or toponymous, coincides fairly well with the beginning of colonisation by Minoan dynasts symbolised by the shaft graves of Mycenæ. (The discrepancy could be better overcome by shortening the generations than raising the date of the tombs.) The great reaction of the Mainland against Cretan domination which resulted in the sack of the Minoan palaces about 1400 B.C. coincides even better with the slaying of the sons of Ægyptus by the daughters of Danaus in the generation of 1400 (Minoan alliance with, if not dependence on, Egypt is clear enough from archæological and hieroglyphic evidence).

So, too, the accuracy of Homer's picture of Achæan society and life is demonstrated along the lines laid down by Allen and Chadwick, but with a fuller mastery and wider use both of the archæological material and of the data supplied by Egyptian and newly discovered Hittite documents. Politically, the Homeric age was a period when foreign dynasts from overseas, Phrygian rather than Hellenic, ruled over Minoanised Greeks as a loosely federated feudal aristocracy. Archæologically, it witnessed the gradual substi-

tution of cut-and-thrust swords for rapiers, of round shields with body armour for long shields, and of iron for bronze.

Very original, too, is the treatment of the fibulæ as illuminating the complex phenomena of this transitional period. Myres regroups several of Blinkenberg's types into larger units the distribution of which is shown to correspond respectively to the area affected by the sea raids mentioned in Hittite and Egyptian documents, to that of the similarly attested land raids into the heart of Asia Minor, and to the Achæan confederacy under foreign dynasts in mainland Greece. The uniformity of the early types in the last-named region is such as to imply quite intimate intercourse between the peoples from Thessaly to Laconia. Yet, apart from their foreign rulers, these peoples must already have been speaking distinct dialects, ancestral respectively to the Ionic, Æolic, and Arcadian of classical times. Myres ingeniously suggests that the 'mixed dialect' of Homer was such a *lingua franca* as was needed to facilitate intercourse in the conditions described. With the break-up of Achæan domination after the Trojan war, specialised local types of safety-pin grow up to symbolise the interruption of intercourse.

The Dorians, too, are recognisable by a special type of fibula, the spectacle brooch, but they did not bring it, as has been usually assumed, from the far north; for Myres would seek their cradle where Greek tradition located it in the peninsula itself, on the north-western fringe of the Achæan confederacy. Nor was the geometric style Dorian, as is generally believed. It was rather the creation of potters, trained in the old Mycenæan tradition, but working for a new public, the product of that dark age of migration the social conditions of which Myres reconstructs most brilliantly. In this style the concentric circle ornament is indeed a contribution from beyond the Balkans, brought by those Lausitz invaders whose presence in Macedonia has been demonstrated by Heurtley and myself. But the Lausitz invasion was just an episode of which Greek tradition preserves memories that lesser authors find it convenient to ignore. The invaders were not Greeks but Thracians, a view which agrees well with my independent conclusions as to the linguistic affinities of Lausitz folk in the Danube valley. Apart from the concentric circle enhancement, the geometric style is essentially Ægean and reaches its highest development in the region least affected by post-Mycenæan intruders, namely, Attica. But in its development the guiding spirit is no longer Minoan or Mediterranean but Hellenic, as Myres shows in a masterly analysis of its content and rhythm. Peculiarly suggestive is his comparison between the rhythm of vase painting and Greek versification. Here lies the clue to the initial question. But to use it the reader must turn to the actual book and read and re-read its arguments, even when they seem irrelevant or repetitive.

V. GORDON CHILDE.

The Importance of Morphology.

Studies on the Structure and Development of Vertebrates. By Prof. Edwin S. Goodrich. Pp. xxx + 837. (London: Macmillan and Co., Ltd., 1930.) 36*s*. net.

THERE is a peculiar irony in the fact that the method of investigation which in the nineteenth century was responsible for the greatest revolution ever effected in man's outlook and appreciation of his own place in Nature should at present be despised and rejected by so many biologists. The publication of a new treatise on morphology is a challenge to the widespread attitude of depreciation of the value of such studies. Perhaps the question at issue can be best defined by a concrete illustration.

During the present century, many hundreds of experimental and clinical investigators have been occupied in the attempt to discover the means whereby co-operation is effected between the pituitary body and the hypothalamus. Yet the unifying device is visible to the naked eye. Prof. Gregor Popa and Dr. Una Fielding have recently described (*The Lancet*, Aug. 2, 1930, p. 238) a hitherto unnoticed and unique series of vessels for conveying to the hypothalamus the colloidal material elaborated in the pituitary, which are virtually the ducts of the hypophysis, the channels in which blood serves the hydraulic function of moving the colloid upward into the brain. This is merely one example of the importance of morphology for the solution of problems of function, and a hint of the risks to which biology would be exposed if what Prof. H. S. Jennings (*Science*, July 30, 1926, p. 98) has called the 'phobia' of antagonism to morphology should be permitted to dominate our work.

It is the business of every department of science to lay a sure morphological foundation upon which to erect the edifice of knowledge. Whether the subject of investigation be the structure of the atom, the anatomy of a crystal, the plan of an

engine, or the architecture of a living organisation, the fundamental consideration is obviously a question of morphology, the neglect of which would stultify any attempt to solve the problems. The physicist, the chemist, the engineer, and the palæontologist do not waste their time in denying the importance of a department of their work which is so essential for the success of their efforts. Yet at the present time we are face to face with the paradoxical phenomenon that many biologists want to repudiate the particular instrument of their subject, which in the hands of Charles Darwin effected the most complete revolution that has ever been made, not merely in the interpretation of living plants and animals, but also in the whole attitude of man to the universe and to the character of his knowledge and sympathies. It is important not to ignore the fact that although Darwin's ideas were in large measure inspired by studies in field biology, in the geographical distribution of plants and animals, and in breeding experiments, his demonstration was based, as he himself so clearly emphasised, on morphology, which in "The Origin of Species" he called "the soul of natural history".

In emphasising the importance of morphology and the danger of neglecting the direct appeal to the observation of concrete facts, however tedious and laborious such a discipline may be, this attitude must not be supposed to involve any failure to recognise the vital importance of the experimental inquiry into the manifestations of life. Most people admit the major interest of the working of a machine and the results which accrue from its use in comparison with its mere structure. But the fascination of watching an aeronaut 'loop the loop' and perform other 'stunts' does not relieve the engineer of the necessity of investigating essential problems of aeroplane construction. Yet there is a widespread tendency to adopt such an attitude in biology—a tendency that is encouraged by the vast importance and brilliance of the results which can often be obtained quickly and easily by experiment. In biology, however, the laborious drudgery of morphological research is a necessary part of most investigations. Moreover, it is a profound mistake to pretend, as not a few zoologists are now doing, that the field of morphology, which has yielded such rich harvests in the past, has been exhausted and is now sterile. It should not be forgotten that a relatively small proportion of the problems of biology is susceptible to inquiry by experiment in comparison with the vast field for research in morphology. The methods which established the fact of evolution have even vaster opportunities for achievement in the future. Almost every discovery in physiology creates new problems for the morphologist—most advances into new territories need for their complete establishment the translation of the results into terms of structure and structural changes. The whole range of palæontological inquiry is primarily morphological.

The attitude of mind that is expressed in the morphology-phobia often assumes a more extreme form in minimising the value of things that can be seen with the naked eye. It is sometimes assumed that anatomical work that does not involve the use of an oil-immersion lens is necessarily futile. The prevalence of the practice of resorting to histological devices before the object of investigation has been thoroughly examined by the naked eye or with a hand lens is responsible for large gaps in our knowledge and a vast number of conventional errors. Not long ago a distinguished surgeon came from Europe to ask for permission to dissect muscles in the human body to compare the lengths of active flesh in the flexors and extensors. When asked why he undertook so long a journey to do what he might equally well have done in the laboratory of his own university (within ten minutes' walk of his house) he replied: "If our professor had an elephant to dissect he would begin by cutting it into sections 10μ thick." This absurd remark unfortunately expresses quite truly the irony of the attitude that is now so prevalent. Even if it be admitted that much of the distrust of morphology may be due to the narrowness and futility of some of the academic morphology of a past generation, this is no excuse for the widespread fashion of depreciation.

It would be possible, if it were desirable, to cite many instances of experimental research the results of which have been utterly stultified by the neglect to take into consideration questions of morphology. What vast accumulations of erroneous inference still encumber the literature of biology because considerations of phylogeny and homology have been ignored! Obvious as they are, these things needed saying to make plain the value and importance of such works as Prof. Goodrich's "Studies on the Structure and Development of Vertebrates". He set out to write a treatise to expound the present state of our knowledge of the comparative anatomy of vertebrates. More than half the volume is devoted to the skeleton, and 512 of the 754 figures with which it is generously illustrated. This is due, not to the assumption that the other parts of the

organism called for a less elaborate treatment, so much as the fact that the attempt to deal with them with the same thoroughness would have taken a lifetime to accomplish.

Prof. Goodrich has performed a very useful service in providing the advanced student of zoology and those engaged in teaching and research in comparative anatomy with trustworthy guidance to our knowledge of the vertebrate skeleton. As it includes an account of the fossil remains of extinct animals, the book is also a treatise on vertebrate palæontology, perhaps the most illuminating and comprehensive work that has been written on that subject. The discussion of the skeletal remains of a large series of extinct animals by a zoologist who is also giving the results of his own investigations on living representatives of the same groups provides a more vital and illuminating interpretation of the fossils than a work dealing with the latter alone. Such a mode of treatment minimises the risk of ignoring the fact that the bones were once clothed with muscles as parts of living creatures. The study of palæontology in association with the anatomy of existing animals represents the essential foundation of evolutionary inquiries. It emphasises the vast significance of morphology as the only key at present available to unlock the mysteries of phylogeny and evolution.

The rest of the book is devoted to the gills and gill-slits, the heart and vascular system, the air-bladder and lungs, the cœlom and diaphragm, the excretory organs and genital ducts, and a brief chapter on the peripheral nervous system and sense organs. No attempt is made to deal with the central nervous system.

In his preface Prof. Goodrich emphasises the fact that his book "is not a complete treatise, but deals with certain subjects and problems of special interest and importance, some of which receive but scant notice in current text-books". This qualification applies not only to the subjects chosen for discussion, but also to his method of dealing with them. Thus his excellent description of the comparative anatomy of the heart, based largely on his own researches, omits any account of the fascinating problem of the connecting systems (the atrio-ventricular bundle).

The difficult questions involved in the evolution of the diaphragm are discussed with great clearness, and, as the author explains with reference to the book as a whole, the lacunæ in our knowledge are defined, but no hasty attempt is made to hide them by premature conclusions.

The least satisfactory part of the book is the final chapter. Perhaps the author would have been better advised to have deferred it until he was ready to link his account of the peripheral nervous system with that of the central organs. The use of the term 'visceral motor' for nerves which supply voluntary muscles of striated type, wholly dissociated from any viscus, is very misleading, even if it is still fashionable among American neurologists. For more than thirty years it has been the practice among most anatomists to distinguish this group as 'lateral somatic', and repeated protests have been made against the application of the word 'visceral' to it.

Prof. Goodrich claims (p. 784) that, while the division of the autonomic nervous system into sympathetic and parasympathetic may be justified on physiological grounds, it is not satisfactory from the point of view of morphology. If, however, the morphologist should differentiate the autonomic fibres, as he suggests, on the basis of the paths—anterior or posterior nerve roots—by which they emerge from the central nervous system, the result will be, not only chaos, but also bad morphology. Clearly homologous fibres in different vertebrates would then have to be placed in different groups. Even in the same animal the cephalic fibres of the accessory nerve would belong to the dorsal root system, from which the caudal fibres of the same nerve would be excluded, although they do not fully acquire the right to inclusion in the ventral root. These considerations reveal the impracticability of Prof. Goodrich's suggestion.

The book in most respects is eminently conservative. In his classification of vertebrates, for example, Prof. Goodrich includes the Tarsiiformes in the sub-order Lemuroidea, although for more than thirty years the need for a special sub-order Tarsioidea to express the admitted facts of morphological distinction has been widely recognised.

These, however, are relatively trivial blemishes in a great achievement, upon which Prof. Goodrich is to be heartily congratulated. The conspicuous quality of the book is the fullness and impartiality of the statement of the present state of our knowledge of vertebrate morphology and the sources of information. Every student of zoology and palæontology should be grateful for this eminently useful book. The excellence of the illustrations, of which there are as many as 754, and the valuable bibliography and scheme of classification of vertebrates are features of the book worthy of special mention.

G. ELLIOT SMITH.

Science and the Layman.

(1) *The Mechanism of Nature: being a Simple Approach to Modern Views on the Structure of Matter and Radiation.* By Prof. E. N. da C. Andrade. Pp. xii + 170. (London: G. Bell and Sons, Ltd., 1930.) 6s. net.

(2) *Matter and Radiation: with Particular Reference to the Detection and Uses of the Infra-red Rays.* By John Buckingham. Pp. xii + 144 + 8 plates. (London: Oxford University Press, 1930.) 7s. 6d. net.

THE ignorance, in matters scientific, of the average intelligent and educated layman is one of the more curious and perturbing features of the age; curious, because science, mostly without intention and as a mere by-product of its activity, has done more to change the structure of society in the last fifty years than statesmen and reformers in all the preceding æons; perturbing, because the discoveries which the scientific worker drops so casually into the stream of knowledge have potentialities, for good or evil, so vast that it seems vitally important that those who are called upon to lead and direct society should have at least sufficient knowledge of the matter to enable them to appreciate these potentialities, and to direct them into wise channels.

Perusal of publishers' catalogues, or of the reviews which appear from time to time in this and other journals, might lead one to suppose that this need had been adequately foreseen and catered for. The fact remains, however, that this large amount of quite competent effort has on the whole failed in its object; the average layman remains still curious and still unenlightened. It is not interest that is lacking. Most of us can, no doubt, recall what should have been pleasant social functions, which have been turned for us into something approaching the horrors of the inquisition by the entirely sincere demands of our friends that we should explain to them some recent achievement in our particular branch of science. The difficulty which almost invariably arises on these occasions and turns what should be a pleasant and grateful task into something like a nightmare, is to find some common basis of knowledge to which we can refer. As Prof. Andrade puts it, in the preface to his admirable volume, "The task is rendered extremely difficult by the fact that the questioner is without the first beginnings of a knowledge of the matter and the method of the science, and is, as it were, like those chemical compounds which are apt and, so to speak, anxious to absorb the vapour of water, but cannot do so easily if they are already very dry; they require a preliminary infection with moisture if they are to drink in with facility a further store". Prof. Andrade's book has been written with the object of providing this necessary preliminary infection with physical science.

(1) "The Mechanism of Nature" is thus an attempt to give the uninitiated but not unintelligent reader an outline of classical and modern physics, to indicate its aims and methods, to expound its basic discoveries and principles, and to show the inter-relations of its various parts. After a preliminary chapter explaining the objects and methods of physical research, the author deals in four brief chapters with the essentials of the four main branches of physics—heat, sound, light, and electricity; and in two concluding chapters with the quantum theory and the atom. To pack so much material into so brief a space might appear to involve an almost impossible degree of compression, but there are no signs of compression or inadequacy in the text. The argument marches steadily step by step, the sentences flow easily, and there is a wealth of pithy but pointed illustrations and similes, which (with or without acknowledgment) we shall certainly see quoted again. So far as it is possible to deal intelligently and intelligibly with a technical subject in non-technical language, the language of the book is non-technical. There is not a single equation to frighten the most timid of readers, nor a single diagram to remind him, perhaps unpleasantly, of the text-books of his youth.

How much will the non-scientific reader carry away from his perusal of the book? It is a little difficult for the scientific reviewer to judge. He will at least realise that Prof. Andrade writes with distinction, and that the subject on which he writes is one which is worthy to occupy the attention of men of culture. If he does not further carry away with him some genuine appreciation of the purpose and content of physics, he may well be advised to give the matter up in despair; he is not likely to encounter an abler guide. "The Mechanism of Nature" is, in short, an exposition of physics which the physicist can recommend with confidence to his non-scientific friends, and by which he may be well content to have his subject judged.

(2) "Matter and Radiation" cannot be recommended with anything like equal confidence. Mr. Buckingham has not Prof. Andrade's art of exposition, and his rambling and pedestrian style makes tedious reading, even where the subject matter is interesting. This is regrettable, because in his two concluding chapters, on the detection and uses of

infra-red radiation, the author has a fascinating subject, and much that he has to tell will be new not only to the general reader but also possibly to some physicists. In this part of the book he writes, if not with distinction, at least with authority and knowledge, and he quite obviously knows so much more about the subject than he has chosen to tell us that he whets rather than satisfies our appetite for information. We could wish for more details than he allows us. It is these later chapters which contain the gist of what the author has to say. The earlier chapters, though they give the title to the book, are but by way of preface, a preface which struck us as being neither particularly well arranged nor particularly well expressed. Mr. Buckingham does not appear to have the proper touch for that kind of writing. We should, however, like to hear more about infra-red rays.

The Mendip Lead Mines.

The Mines of Mendip. By J. W. Gough. Pp. x+269. (Oxford: Clarendon Press; London: Oxford University Press, 1930.) 15*s*. net.

THE observant traveller who crosses the Mendip Hills cannot fail to notice the broken ground, so-called 'grubby or gruffy ground', which his map tells him represents the scene of ancient lead workings. Efforts to acquire fuller knowledge of these met with only partial success until the appearance of Mr. Gough's book, which obviously fills a definite want. The Mendip lead mines date from at least the second century B.C.; they have had a lengthy history, not without many vicissitudes. A good deal of the mining followed veins running near the surface, working either shallow trenches a few feet deep or small pits close to one another running in lines across the fields. The principal lead ore was galena.

In Elizabethan times calamine, a carbonate of zinc, was also worked in the Mendips, and this ore was of much importance in the middle of the eighteenth century when the lead industry was sinking.

The story of a mining field worked for two thousand years is full of interest in every direction. We know from Pliny that Britain became the chief source of lead in the Roman Empire: it was found at the surface of the ground so abundantly that a law was spontaneously passed to limit production. The mines were worked by slave labour or prisoners of war; they were imperial property and their produce was stamped with the Emperor's name; from time to time pigs so marked have been found. The Roman headquarters were at Charterhouse, but very little is known about the site.

Naturally, there has always been conflict between the miners and the farmers, particularly over such questions as common rights and the very serious risk of lead poisoning due to stream pollution or the escape of fumes during smelting. Mr. Gough tells us of some of the troubles during the sixteenth century and later; he further leads us on a side issue into the subject of dowsing for metals, which persisted from the date of its first mention about 1638 down to the last days of the mining industry.

Of the mines in the Middle Ages the knowledge is fragmentary, monotonous, and mainly financial. For a long time they were leased to the Bishop of Bath. Almost nothing is known about the methods of mining and smelting, though there is plentiful information available about the silver-lead mines in South Devon, no doubt because they were Royal mines. The Mendip industry had its own laws and customs, with special courts to enforce them.

Lead mining was at its pride between 1600 and 1670, when every foot of any rich patch of ground was exploited to the utmost, workmen digging pits within a few yards of each other; this is the explanation of the condition of the ground to-day with its profusion of mounds and hollows. Disputes were endless, as the records of the courts show, but the mines were never monopolised by any one big firm such as the Mines Royal which owned all the copper mines in the Lake District.

Our technical knowledge of the mines at this time is due to an elaborate list of questions published in the first number of the *Philosophical Transactions* of the Royal Society, by Boyle, entitled "Articles of Inquiries touching Mines". It was answered by Joseph Glanvil, the vicar of Frome, in two papers which appeared in the second and third volumes of the *Philosophical Transactions*.

By 1680 the readily accessible lodes were exhausted as the result of this intensive working and the deeper pits were much troubled with water flowing into them: various efforts were made to combat this, but none of them achieved commercial success. In later years the poor quality of the Mendip lead in comparison with that from Derby or Flintshire made it impossible to carry the heavy overhead charges of modern appliances. In the nineteenth century the Mendip lead, which contained arsenic, was practically all used for making shot in Bristol; it was too hard for the London plumbers to use for sheeting.

The ancient courts with their executive officers,

the records of which tell us so much of the financial and administrative work, disappeared together with the mines. Both lead and zinc had been kept going by a system of protection, and with the advent of free trade their days were numbered, though in any case the old-fashioned individual shallow mining could not have long persisted.

The long story of the Mendip mines is an attractive one, embracing many fields of science, well worth the telling in detail. Our epitome has indicated the breadth of Mr. Gough's treatment, and he is to be congratulated on the thoroughness of his achievement. E. F. ARMSTRONG.

Our Bookshelf.

(1) *Fortschritte der Geologie und Paläontologie.* Herausgegeben von Prof. Dr. W. Soergel. Band 8, Heft 24: *Die tektonische Entwicklung eines Schollengebirgslandes (Vogelsberg und Rhön).* Von K. Hummel. Pp. viii + 234 + 3 Tafeln. 18 gold marks. (2) Band 8, Heft 25. *Das varistische Bewegungsbild entwickelt aus der Inneren Tektonik eines Profils von der Böhmischen Masse bis zum Massiv von Brabant.* Von Hermann Scholtz. Pp. ix + 235-316 + 8 Tafeln. 15 gold marks. (Berlin: Gebrüder Borntraeger, 1929 and 1930.)

Two new parts of this serial form interesting contributions to the geology of south-western Germany and the Rhinelands. They both illustrate the increased recognition of the direct influence of earth movements on topography.

(1) Prof. Hummel of Giessen deals with the Vogelsberg in Upper Hesse and the Rhön Mountains along the western frontier of Bavaria and Thuringia, and shows how their topography is dominated by block movements. The area includes the extensive basaltic eruptions to the north-east of Frankfort, and he discusses the relation of the tectonic and volcanic processes. He considers the northern end of the rift-valley of the Rhine, of which the margins have been raised by uplift. Though the main direction of the fractures and rift-valley of the Rhine is to the north-north-east, the course of the valley is modified by the Variscan folds and in part takes their direction. The river system of the Upper Main, however, is less dependent on the tectonic structure than on the basalt eruptions, as the streams are mostly radial from the volcanic piles. The work is accompanied by three maps illustrating the relief of the Vogelsberg and the Rhön Mountains and the relations of the volcanic rocks of that area to the river system.

(2) The monograph by Scholtz is a study of the distribution of various pressure phenomena among the older rocks from Brabant to Bohemia. He classifies them into three types, cleavage, pressure-fractures (*Schubklüftung*), and cross-fractures (*Querklüftung*); he describes these structures in detail, and shows their relation to the Variscan and Alpine movements. The work is well illustrated by photographs, diagrams, and maps.

Annual Survey of American Chemistry. Vol. 4: July 1, 1928, to December 31, 1929. Prepared under the Auspices of the Division of Chemistry and Chemical Technology, National Research Council. Edited by Clarence J. West. Pp. 549. (New York: The Chemical Catalog Co., Inc., 1930.) 4 dollars.

THE object of this survey is " to present throughout a period of years a complete survey of American chemistry ", not, it will be noted, an American survey of chemistry, quite another and a much more acceptable thing to non-American chemists. The endowment of science with a national label would be open to criticism even were it admitted that chemical progress, like creative art or even mechanical invention, can be so characterised. In point of fact, one step depends too much on the success of another; moreover, the search for fundamental truth in scientific fact, whether it proves a source of strength or weakness, a curse or a blessing, according to the use made of it, is as little concerned with political frontiers as is the legislature with the laws of thermodynamics. Hence whatever value the series under review possesses—and its value in certain directions is not denied—the survey can scarcely be regarded as a significant contribution to the world's literature of chemistry. The limitation of its general value is admitted in the foreword: " The progress in any branch of chemistry is not confined by the boundaries of any one nation ", whilst the sentence which follows exhibits a proper sense of patriotism: " This fact means that in a short time fundamental progress abroad is reflected by the work carried on in America. Therefore a careful annual survey of American chemistry possesses only a certain lag. . . ." Incidentally, however, not all the authors mentioned are United States citizens, and not all of the journals cited are of American origin. The present volume covers a period of eighteen months in order that succeeding volumes may review a calendar year instead of a fiscal year. There are 43 chapters covering a great variety of subjects in pure and applied chemistry, and an author index is appended. A. A. E.

The Sea. By H. A. Marmer. Pp. x + 312. (New York and London: D. Appleton and Co., 1930.) 10*s*. 6*d*. net.

THERE are many popular books on the sea, but they commonly err in trying to combine its science in a single volume. The physics and chemistry are often so cut down that the biologist is not given the basal facts on which the understanding of his problems depends, while the general reader is left with almost nothing. The author of the volume under notice, who is assistant chief of the famous Coast and Geodetic Survey of the United States, omits biology altogether, and the result is a most readable volume that should appeal to every traveller.

The volume is written simply and sincerely, and has all the requisite illustrations. The Sargasso sea is mentioned for its extraordinary clearness, a white disc being visible when lowered to 200 ft., its high temperature and salinity, and its relative

motionlessness. Its weed is in small patches, and, while sometimes reinforced from the shallow reefs, ordinarily propagates vegetatively. The depths of the sea should shortly be better known by sonic sounding, which has already given us 35,400 ft. (6·7 miles) near the Philippines. It also suggests that the gentleness of relief of the sea bottom has been very greatly overestimated. The yearly, monthly, and daily variation in sea-level is brought out and clearly requires careful study. The tides are treated well, but we miss the familiar world chart, which serves to explain their origin and curious effects found in the North Atlantic.

We should have welcomed a discussion of the tidal currents in relation to depth and obstructions. A fuller account of 'the waters of the depths' and of their circulatory movements would excite the imagination of the reader. The genesis of the Gulf Stream, the earth's magnetism, and the characters of enclosed seas and their opening straits occur to us as 'larger features' than 'Legendary Isles' and accounts of polar explorations. A chapter on the U.S. Coast and Geodetic Survey would also be of interest as it would necessarily contain the history of the modern exploration of coastal waters.

Physiology and Biochemistry in Modern Medicine. By Prof. J. J. R. Macleod, assisted by Roy G. Pearce, A. C. Redfield, N. B. Taylor, and J. M. D. Olmsted, and by others. Sixth edition. Pp. xxxii + 1074 + 9 plates. (London: Henry Kimpton, 1930.) 42*s.* net.

PROF. MACLEOD'S text-book is now well established in the literature, in fact, it has reached its sixth edition in the course of twice as many years. It blends under one cover general and special physiology and biochemistry and applied or clinical physiology: it is larger than works devoted to clinical physiology, but makes no attempt to deal in any detailed manner with many of the problems of specialised physiology. In fact, this science has now so many branches, general, biochemical, and histological, that it has become impossible for one volume to deal adequately with all. Prof. Macleod has performed the useful service of selecting from the mass of literature material suitable for welding into a whole as human physiology, which is almost the same as clinical medicine, when healthy, and not diseased, individuals are the subject of study.

This edition has been thoroughly revised and in places rewritten: but in comparison with the total bulk of our knowledge, certain recent discoveries, which have loomed large in the public eye, assume their more correct proportions. The general plan of the work is well known: it is divided into ten parts devoted to the physicochemical basis of physiological processes, the blood and lymph, the neuromuscular system, the special senses, circulation, respiration, digestion, excretion, metabolism, and the endocrine organs. It should be in the hands of all medical students and teachers of physiology and can be read with profit by all interested in the scientific basis of modern medicine.

Engineering Electricity. By Prof. Ralph G. Hudson. Second edition. Pp. viii + 214. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1928.) 12*s.* 6*d.* net.

THIS book is intended primarily for the junior and senior engineering students of the Massachusetts Institute of Technology who are not specialising in electrical engineering. It contains an outline of lectures previously given by the author. These lectures are now discontinued, and in their place nine pages of the text are assigned each week for home study. The class-room exercises consist of three 'recitations' and one problem section per week. An independent laboratory course covers the same ground and follows the class exercises. The keynote of the work we are told in the preface is brevity, and since the students are nearing the end of their college studies the statements are made as rigorous as possible. Chap. xvii. is devoted exclusively to illustrations illustrating all kinds of electrical apparatus.

Apparently 'weatherproof' insulation and 'slow-burning' insulation are distinguished by the intensity of the shading. In Chap. xviii. a hundred practical problems are given. As a class-book we think this book will be useful. But considering its size we think that 12*s.* 6*d.* is far too much to charge for it.

Disease and the Man. By Prof. George Draper. (The Anglo-French Library of Medical and Biological Science.) Pp. xix + 270 + 19 plates. (London: Kegan Paul and Co., Ltd., 1929.) 12*s.* 6*d.* net.

DR. DRAPER provides us with a very interesting sidelight on the relation between disease and the type, physical and mental, of the patient. This book forms a useful extension to disease of the work of Kretschmer on the relation of bodily type to character. Anthropometric data are all too little used in connexion with disease. The author presents series of cases of gastric ulcer, gall-bladder disease, pernicious anæmia, tuberculosis and nephritis, and points out the varying physical characteristics which are common to these disease groups. The relation between psychological characters and physical disease is also considered.

The Planktonic Diatoms of Northern Seas. By Dr. Marie V. Lebour. (The Ray Society Volume 116 for the Year 1929.) Pp. x + 244 + 4 plates. (London: Dulau and Co., Ltd., 1920.) 12*s.* 6*d.*

THIS book is indispensable to all biologists interested in the life of the ocean. The families, genera, and species are clearly defined and well illustrated, their distribution properly recorded. There is a good bibliography. An introductory chapter gives a brief account of the general morphology, reproduction, and nutrition. We learn that all diatoms without chromatophores are saprophytic. Some have fungi and other algæ as parasites, while a dinoflagellate is found on *Chaetoceros*. There are several symbionts, especially flagellates, while some diatoms have special associations with infusorians.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Constitution of Molybdenum.

FOLLOWING the successful analysis of chromium announced in NATURE of Aug. 9, I have now been able to apply similar methods to molybdenum. The mass-spectrum of this element is a remarkable one, and the credit of its discovery rests with Dr. A. v. Grosse, who prepared the specimen of molybdenum carbonyl with which the work was done.

In contrast to the theoretical prediction of Russell (NATURE, Oct. 20, 1923) molybdenum has no less than seven isotopes, and the group indicates relative abundance relations far closer than those of any other multiple element so far investigated. Owing to incidental difficulties, which I need not enumerate here, measurements could not be made so accurately as usual. The following are the mass numbers and their approximate percentage abundance:

92	94	95	96	97	98	100
14·2	10·0	15·5	17·8	9·6	23·0	9·8

By comparison with the doubly charged mercury group the packing fractions of Mo^{98} and Mo^{100} were provisionally estimated. Both appear to be about $-5·5$, a considerably smaller negative value than that expected from the curve. From these values, correcting to the chemical scale we get:

$$\text{Atomic weight of Mo} = 95·97 \pm 0·05$$

in good agreement with the figure 96·0 obtained by chemical methods.

Two of the isotopes are isobaric with the well-established isotopes of zirconium 92 and 94, and a third with the doubtful one 96.

F. W. ASTON.

Cavendish Laboratory,
Cambridge, Aug. 21.

The Period of 'Actino-uranium' and its Bearing on the Ages of Radioactive Minerals.

FROM the mass-spectrum of the mixture of lead isotopes isolated from Norwegian bröggerite Dr. F. W. Aston (NATURE, Mar. 2, 1929, p. 313) estimated the relative proportions of the individual isotopes to be approximately

Pb^{206}	Pb^{207}	Pb^{208}
86·8	9·3	3·9

The line 207 is referred to the end-product of the actinium series, and the latter is regarded as having its origin in an isotope of uranium (*actino-uranium*). In the course of a discussion of the significance of Aston's results, Sir Ernest Rutherford tentatively estimated the half-value period of the hypothetical isotope (NATURE, Mar. 2, p. 314; 1929). Taking the period of uranium I as $4·5 \times 10^9$ years, he found a probable value of $4·2 \times 10^8$ years for the period of actino-uranium. If this estimate (based on the unexpectedly high amount of Pb^{207} found by Aston in the bröggerite lead) be of the right order, then it follows that Pb^{207} has been generated in minerals more rapidly from the actinium series than Pb^{206} from the uranium series. In calculating the ages of radioactive minerals it would therefore be necessary to allow for this difference. The object of this letter is to direct attention to another line of evidence from which it can be inferred that the periods of uranium I and actino-uranium are probably more nearly equal, and that no correction to the calculated ages of minerals is required in the present state of our knowledge.

From the approximate constancy of the ratio of actinium or protoactinium to uranium in minerals, it has generally been accepted that the percentages of atoms disintegrating via actinium and radium respectively are about 3 and 97. This ratio has recently been investigated afresh by J. E. Wildish (*Jour. Am. Chem. Soc.*, **52**, Jan., 1930, p. 163), who finds that the number of atoms of protoactinium disintegrating per 100 atoms of uranium I ranges in five different minerals from 1·47 to 5·16. Incidentally, this departure from constancy strengthens the growing belief that the actinium series is not a branch of the uranium series; it also raises a doubt whether the actinium parent can be an isotope of uranium. The immediate point of importance, however, assuming that actinium produces Pb^{207}, is that the number of atoms of Pb^{207} produced in radioactive minerals at the present time is 3 ± 2 for every 100 atoms of Pb^{206} produced from uranium I. If both uranium I and actino-uranium disintegrate at about equal rates, then in Pre-Cambrian minerals the percentage of accumulated Pb^{207} to accumulated Pb^{206} should also fall within this range. If, on the other hand, Rutherford's suggestion is true, that actino-uranium disintegrates more rapidly than uranium I, then the proportion of accumulated Pb^{207} should be definitely higher. For a few minerals data are available which permit a test of these alternatives.

Let A = atomic weight of the mixture of lead isotopes isolated from a mineral;

$$\left.\begin{array}{l} a = \text{percentage of } Pb^{207} \\ b = \text{percentage of } Pb^{206} \\ c = \text{percentage of } Pb^{208} \end{array}\right\} \begin{array}{l}\text{in the mixture}\\ \text{of lead}\\ \text{isotopes.}\end{array}$$

Then we have

$$207a + 206b + 208c = 100A$$

$$a + b + c = 100$$

$$\frac{a+b}{c} = \frac{U}{0·38\,Th}$$

where U and Th represent the respective percentages of uranium and thorium in the mineral. The third equation is based on the fact that the lead-producing capacity of thorium is only 0·38 times that of uranium which, as chemically determined, includes actino-uranium as well as uranium I.

From the three equations we find

$$c = \frac{100}{\left(\frac{U}{0·38\,Th} + 1\right)}$$

and

$$a = 100(A - 206) - \frac{200}{\left(\frac{U}{0·38\,Th} + 1\right)}$$

The packing-effect is clearly important here, for if the atomic weight of Pb^{206} be 206·016 (as suggested by Aston), then the value of a will be diminished by 1·6, which is a considerable part of its total value. In the following table a is therefore calculated from the expression

$$a = 100(A - 206·016) - \frac{200}{\left(\frac{U}{0·38\,Th} + 1\right)}$$

	I.	II.	III.	IV.
A = At. Wt. of Pb	206·048	206·046	206·071	206·122
U per cent	c. 72	73·07	66·88	65·28
Th per cent	0·00	0·28	1·89	6·86
$\frac{U}{0·38\ Th}$	∞	686·75	93·12	25·04
a (Pb^{207})	3·20	2·71	2·38	2·92
b (Pb^{206})	96·80	97·14	96·56	93·24
c (Pb^{208})	0·00	0·15	1·06	3·84
$\frac{100\,a}{b}$	**3·3**	**2·8**	**2·5**	**3·1**

IV.—Bröggerite, Raade, Moss district, S.E. Norway. Analyses, Gleditsch: *Norsk. Videns Akad.*, Oslo, I Mat. Nat. Kl., No. 3, 1925; At. Wt., Richards and Wadsworth: *Jour. Am. Chem. Soc.*, **38**, p. 2613, 1916.

In addition to the minerals listed there are some others of Pre-Cambrian age for which analytical and atomic weight data have been recorded. For the lead from the uraninite of Sinyaya Pala, East Karelia, Nenadkevitch gives two atomic weight determinations, 206·02 and 206·11 (*Min. Abstracts*, London, **3**, p. 263; 1927). On these results, $100a/b$ is between 0·2 and 10 with an average of 5. The cleveites of the Arendal district investigated by Mlle. Gleditsh (*op. cit.*) give very low or very high results for a, probably because the minerals are altered, in which case the method of calculation is invalid. Similarly, the thorium minerals of Ceylon are unsuitable as a test. They, too, are altered, and for each of them a turns out to be negative. So far as I am aware, only the four minerals given in the table can be appealed to safely for a solution of the problem under discussion.

The ratio $100a/b$, which is the ratio of accumulated Pb^{207} to accumulated Pb^{206}, is thus found to vary between 2·5 and 3·3. This clearly means that through the greater part of geological time the proportion of Pb^{207} generated in minerals has been of the same order as that generated at the present time. The adoption of a smaller value for the factor here taken as 0·38 (Kirsch favours a value near 0·25) leads to the same conclusion. There is certainly no indication that Pb^{207} was produced more rapidly 10^9 years ago than it is now, and we may therefore conclude:

1. That Aston's estimate of 9·3 per cent for the Pb^{207} in Norwegian bröggerite is too high to be considered representative;
2. That Rutherford's resulting estimate for the period of actino-uranium is too low;
3. That the periods of both uranium I and actino-uranium are probably of the same order; and
4. That in consequence there is at present no necessity to make any correction for the actinium series in age calculations when uranium has been determined chemically.

Catalysis.

IT is well known that only a few of the collisions between reacting molecules result in a reaction taking place, a certain 'energy of activation' being necessary to make the collision effective. The reducing factor for the case of three degrees of freedom is Exp. $(-E/RT)$ where E is the energy of activation. The value of E appears to be of the order of some tens of thousands, say, 50,000 calories per molecule. For a reaction at 1000° Abs., the index is of the order of -24.

Any cause which reduces the degrees of freedom by unity would reduce this index by one-third part; a reduction of two degrees of freedom would reduce it by two-thirds of its value and if all degrees of freedom were removed the index would disappear entirely. With the above value of E, the exponential factor in the several cases becomes (1) $3·77 \times 10^{-11}$ (2) $1·12 \times 10^{-7}$, (3) 3×10^{-4} and (4) unity, the first being the value met with in normal gas reactions.

Now an adsorbed layer of oriented polar molecules with their proper poles all pointing outwards toward a surrounding gas will tend to swing the colliding molecules round so that instead of it being a question of chance, it may become a certainty that the suitable poles for reaction to take place will be presented to one another; in this case, the rate of reaction passes from the first to the second of the above categories and it is therefore increased in a ratio of about 30,000 and we have a reasonable case of catalytic acceleration. If, further, the forces experienced by an oncoming molecule could swing it round the axis of approach so that it inevitably 'fits' its future partner, a second degree of freedom passes into the category of certainties and we have case (3) and the catalytic activity is multiplied by 10^9; and so on.

On the other hand, catalytic 'poisoning' occurs when the wrong poles are made inevitably to present themselves. A single layer might be quite effective in stopping a reaction; and a *very much smaller* quantity might reduce the rate a few hundred or thousand times, and this, in commercial practice, is equivalent to stopping it altogether.

It is quite commonly supposed that the facts of catalysis require a reduction in the value of E, whereas the above considerations show that E may remain of its normal value. To point this out is the main object of this letter. There is still considerable mystery enshrouding E. It is taken to be energy which a molecule must acquire before it can be in a reactive state; on the other hand, in the formula, it is calculated from the energy of molecular agitation. The need for a minimum velocity of agitation becomes clearer if we think of the corresponding case of expulsion of electrons by colliding α-particles: only particles of certain minimum velocities can penetrate the atoms to the requisite levels. Something of the same kind may be conceived as taking place in atomic interchange. If so, it is unlikely that the quantity E should change and considerations such as that taken into account in this communication become all-important.

ALFRED W. PORTER.

The Electrical Properties of Active Nitrogen.

WE have recently been investigating the electrical conditions obtaining in active nitrogen, and our findings seem of sufficient interest to justify a preliminary note thereupon. They are as follows:

(1) Removal of all charged bodies from a stream of active nitrogen is without effect upon its chemical properties, or the concentration of the chemically active species. Lord Rayleigh has already found that complete removal of ions from the glowing gas does not diminish its luminosity or its ability to develop spectra of other substances, but no examination has hitherto been made of any possible effects upon the

chemical activity. This result is in accordance with expectations.

(2) Constantinides has already found that the current which passes between two electrodes of different areas bathed in the afterglow is proportional to the area of the *cathode*, and has therefore concluded that the conductivity of active nitrogen is due to emission of electrons by the metal, either photoelectrically or else under bombardment by the luminous gas. We find that if the electrodes are placed in a thin quartz vessel surrounded by, but not actually containing, glowing nitrogen, no current passes, even under the most varied conditions of experiment both in the electrode chamber and outside. We therefore conclude either that the effect is produced by light of a wave-length less than 1400 A., or that the second of Constantinides' theories is correct, and that it may be regarded as evidence for the presence of a metastable form of nitrogen which is deactivated by the metal surfaces, with emission of electrons, as in the experiments of Oliphant upon metastable atoms of helium. When the electrodes are immersed in the glowing gas, the current depends upon the area of the cathode, as found by Constantinides, but also upon the metal of which it is composed. Attempts are being made to correlate it with the work-function of the metal; such estimates as we have been able to obtain suggest something greater than 4 volts as the minimum energy of the metastable body causing the emission of electrons.

(3) When the glow is destroyed by heating the gas before it reaches the electrodes, the conductivity also vanishes, but the concentration of chemically active nitrogen remains unchanged, as already found by one of us (E. J. B. W.); the observation seems to indicate that another modification of nitrogen is present which is chemically inactive, but able to cause metals to emit electrons, and possesses an energy of not less than about 4 volts. It may be noted that the Cario-Kaplan theory provides for the existence of metastable molecules of *c.* 8 volts, the destruction of the glow by heat being due on the same theory to the deactivation of these molecules on hot surfaces.

(4) We have been able to correlate the observed conductivity and glow intensity with the nature and concentration of the photogens, or other gases, present in active nitrogen.

Raman Displacements and the Infra-red Absorption Bands of Carbon Disulphide.

THE Raman spectrum of carbon disulphide has been determined by a number of observers (Gavesan and Venkateswaran, NATURE, **124**, 57; 1929; Petrikaln and Hochberg, *Zeit. phys. Chem.*, B. **3**, 217; 1929; and by Schaefer, Matossi, and Anderhold, *Phys. Zeit.*, **30**, 584; 1929). In all cases an intense line displaced by 654-658 cm.$^{-1}$ was observed, together with a weak line corresponding to 795-807 cm.$^{-1}$. The spectrum is of considerable interest, as it has been impossible up to the present to reconcile it with the observed infra-red spectrum as determined by Coblentz.

We have recently reinvestigated the absorption spectrum, using the vapour of carbon disulphide, and have explored the region from 1μ to 22μ. In this range there are four bands, *A*, *B*, *C*, and *D* at 878, 1522, 2179, and 2335 cm.$^{-1}$ respectively; of these, owing to its great intensity, *B* is probably a fundamental band, ν_3. Now it has been previously assumed (Ghosh and Mahanti, NATURE, **124**, 230; 1929; and *Phys. Zeit.*, **30**, 531; 1929; Snow, *Proc. Royal Soc.*, A **128**, 311; 1930) that the two Raman lines are in effect a doublet of the same nature as is given by carbon dioxide, and that this type of Raman spectrum is characteristic of such linear molecules: on this supposition Ghosh and Mahanti have averaged the frequencies of the two Raman lines and attempted to deduce the infra-red spectrum with this value as a fundamental. Nitrous oxide gives only one line, however, and we believe that the two lines for carbon disulphide have different origins. We postulate two additional fundamental frequencies, $\nu_2 = 655$ cm.$^{-1}$ (optically inactive), and $\nu_1 = 150$ cm.$^{-1}$ approximately. The spectra can now be summarised as in the table below. All frequencies are in wave numbers.

THE ABSORPTION SPECTRUM OF CARBON DISULPHIDE VAPOUR IN THE INFRA-RED.

Infra-red Band.	Raman Line.	Origin.	Calculated Value
(150)	—	ν_1	—
—	655	ν_2	—
—	800	$\nu_1 + \nu_2$	805
878	—	$\nu_3 - \nu_2$	867
1522	—	ν_3	—
2179	—	$\nu_3 + \nu_2$	2177
2335	—	$\nu_3 + \nu_2 + \nu_1$	2322

Some bands isolated by Coblentz seem to be characteristic of the liquid state as they are absent from our spectrum.

We would add that we have resolved with certainty two of these bands into *P* and *R* branches with a frequency difference of 12-13 cm.$^{-1}$. Carbon disulphide, then, is a rectilinear molecule with one moment of inertia, the value of which is approximately 312×10^{-40} gm. cm.^{2}

Absorption of Sound at Oblique Incidence.

IN the issue of NATURE for July 5 Dr. E. T. Paris discusses some recently published work at the Bureau of Standards on the absorption of sound at oblique angles of incidence. A detailed discussion of Dr. Paris's criticism of our experimental technique does not seem called for at present. These experiments are pioneer work on this subject, and it is much to be desired that others should give the question experimental attention, the more so because the Bureau's results are at variance with previous theoretical conclusions.

Paris (*Proc. Roy. Soc.*, A, **115**, p. 407; 1927) and Larmor (*Proc. Camb. Phil. Soc.*, **27**, part 2, p. 231; April 1930) have investigated the subject mathematically, and have reached conclusions which fail to agree, not only with the Bureau of Standards' results, but also with each other. For grazing incidence, Larmor finds that the absorption should be infinite, while Paris comes to the conclusion that it should be zero.

It would be very desirable that the reasons for this discrepancy in the two theories should be cleared up. It is possible that there is a fundamental inconsistency in the assumption of potential flow and absorption at reflection. This is pointed out in the Bureau of Standards' publication (Bureau of Standards *Journal of Research*, Feb. 1930). Sound absorption depends

upon friction in capillary channels, and must lead to rotational motion, not only in the absorbing material but also throughout a thin layer close to the surface; and in the presence of rotational motion there can exist no velocity potential.

As a similar phenomenon, the Prandtl boundary layer in aerodynamics may be cited. Although at some distance from an airfoil the motion of the air is well represented by potential theory, yet in the immediate neighbourhood of the surface the potential theory fails to give even a rough approximation to the actual motion. It is to the failure of the fluid to maintain irrotational (potential) flow in the neighbourhood of the surface that the whole lift and drag of an airfoil is to be ascribed.

It seems probable that an adequate theory of sound absorption must contain as an essential part a thin layer of air in rotational motion.

Influence of Nitrogen Dioxide upon the Ignition Temperature of Hydrogen-Oxygen Mixtures.

MR. H. J. SCHUMACHER has proposed (NATURE, July 26, p. 132) an explanation of the explosive action of nitrogen dioxide in hydrogen-oxygen mixtures at temperatures in the neighbourhood of 380° C. The ignition occurs according to Thompson and Hinshelwood between sharply defined limiting pressures of nitrogen dioxide. Schumacher's explanation is based upon the assumed competition of the following two reactions:

(1.) $NO_2 + O = NO + O_2 (+51 \text{ cal.})$
(2.) $H_2 + O = OH + H (+8 \text{ cal.})$

It is assumed that the oxygen atoms are produced from nitrogen by collisions with 'hot' molecules. Photochemical production of even greater numbers of oxygen atoms [1] than could originate in this way has been found unable to cause explosions at temperatures at which nitrogen dioxide in the correct concentrations is effective. On the other hand, the formation of water in the region immediately outside both limiting concentrations falls to negligible values, in contradiction to that which would be expected from the mechanisms (1) and (2).

The whole phenomenon is to be attributed to a process occurring at the wall of the reaction chamber [2] where the so-called non-stationary explosions are stimulated by very small quantities of nitrogen dioxide added to the gas and hindered by greater additions which poison the surface.

Boscovich and Theories of Light.

IN histories of science full justice is done to the perspicacity of Newton in suggesting a compromise between the corpuscular and undulatory theories of light. According to Mr. Dampier-Whetham, "the most striking feature about Newton's theory is its resemblance to quite modern conceptions". Speaking elsewhere of recent views about light, he refers to one which postulates "a complex of particles and waves which recalls even more vividly Newton's ideas".

No mention, however, is made of the efforts of Boscovich to give a working hypothesis which would combine the good points of both conceptions. In Mr. Dampier-Whetham's book "A History of Science" Boscovich is mentioned only in connexion with his theory of matter and then the name is spelled Boscovitch. In his "Philosophiæ Naturalis Theoria" (my copy is dated Vienna, 1759, therefore one year after the first edition) Boscovich certainly sums up in favour of a corpuscular theory and "contra omnes alias hypotheses, ut contra undas, per quas olim phænomena lucis explicare conatus est Hugenius". But he is aware of the strong points of the wave theory and suggests that the light particle has an oscillatory movement. Doubtless the idea is crude and is founded chiefly on the assumption of unequal initial velocities of the components of each particle when expelled from the light source; but it was considered sufficiently important to be noticed by Thomas Young.

W. A. OSBORNE.
University of Melbourne,
June 26.

THE extract from the writings of Boscovich which Prof. Osborne quotes is interesting. Until the reason for the rectilinear propagation of light-waves was explained by the work of Young and Fresnel on interference, the difficulties of an undulatory theory were very great, and it is not surprising that Boscovich, like Newton, "sums up in favour of a corpuscular theory". His attempt to combine with it some of the advantages of a wave theory as described by Prof. Osborne seems to me less successful than the method adopted by Newton.

C. DAMPIER-WHETHAM.

Curling.

IN NATURE of Mar. 15 there appeared a letter by W. H. Macaulay and Brig.-General G. E. Smith in which a theoretical treatment of curling was given. The results or conclusions were so nonconcordant with the known behaviour of curling stones that the authors ended their letter by raising a question as to what important feature of the motion had been overlooked.

As it is obvious that the writers were unaware of the experimental study of this problem made by myself, may I direct attention to the report on this work which was published in the *Transactions of the Royal Society of Canada*, Vol. 18, p. 247; 1924. The experimental work involved not only observing the motion of curling stones on standard ice sheets such as are regularly employed in curling, but also a study of torques transmitted to curling stones by a motor-driven rotating ice sheet. The results definitely pointed to the conclusion that the explanation of the curvature of the path taken by a stone possessing both translational and rotational velocities was to be found neither in the suggestion of Sir Gilbert Walker that the friction was greater on the rear edge of the cup nor in any differential air pressure effects as others have suggested, but rather hinges on the very rapid increase in the ice-stone friction as the velocity of the stone with respect to the ice becomes low and approaches zero. This means that the edge of the cup on which the tangential velocity due to the rotation is in a direction opposite to the direction of the translational velocity of the stone, that is, the slow edge of the cup, will experience a greater friction than the diametrically opposite portion of the rim. The

difference between the two forces—in other words the asymmetry of the retarding forces—and the resulting curvature in the path taken therefore depend not only on the 'speed' and the 'spin' given the stone, but also on the ice conditions, just as is observed in practice.

Holes produced in Ground by Lightning Flash.

DURING a thunderstorm of considerable severity which passed over a district near Rothbury, Northumberland, on the afternoon of Tuesday, Aug. 12 last, a flash of lightning apparently struck the ground and produced in it a vertical hole, approximately circular in section, and found on measurement to be 1 ft. 11 in. in depth. The hole is tapered, being 6 or 7 in. in diameter at the surface and about 2 in. in diameter at a distance of a foot below the surface. The hole was made in a grass field which lies on sloping ground and which consists of light loamy soil. The field, about 17 acres in extent, is almost surrounded by trees (chiefly firs). The position of the hole is not at the highest part of the field, but several feet below the highest level, while beyond the field are hills and moorland rising to a height of some hundreds of feet above the field. In the field is a clump of fir trees, close to which is a small hut, distant from the hole about 60 yards. A gamekeeper who was in the hut at the time the flash occurred was thrown violently backwards by the concussion which followed the flash, although he is confident he did not experience any electric shock. A hen in a coop about 10 ft. from the hole was killed, as also were four young pheasants, one inside the coop, and three near, but outside, it. A heavy rain accompanied the storm, which might account for the absence of any sign of burning round the hole. There were also two smaller holes formed at distances respectively of 4 ft. 6 in. and 7 ft. 6 in. from the main hole. The first was nearly horizontal, was open on the surface for some 10 in., and, for the few inches where it penetrated the surface, was about half an inch in diameter. The second was smaller still, slightly inclined to the vertical, and approximately a quarter of an inch in diameter and some two or three inches deep.

Apart from the well-known phenomenon of 'fulgurites', it would be interesting to learn if effects similar to those above described are familiar to meteorologists.

WILFRED HALL.

Hepple, Northumberland,
Aug. 26.

Adsorption of Hydrogen and Carbon Monoxide on Oxide Catalysts.

IN the course of experiments on the heats of adsorption of hydrogen and carbon monoxide on oxide catalysts, it was observed that these gases behaved in a curious manner on desorption. Hydrogen or carbon monoxide adsorbed at room temperature on the $ZnO - Cr_2O_3$ catalysts at equilibrium pressures of 10^{-3}-10^{-4} cm. was evolved on raising the temperature to 100°-120°, but within a period of 20-30 minutes, it was readsorbed on the surface giving a hard vacuum in the containing vessel. On further raising the temperature, no gas was evolved until 350° C., when water vapour or carbon dioxide respectively was liberated. Mixtures of hydrogen and carbon monoxide behaved similarly, being evolved and readsorbed at 100°-120° C. and finally at 350° C. being converted into a mixture of water and carbon dioxide, no appreciable quantities of organic compounds being formed.

Hydrogen on copper oxide gives similar phenomena, as was shown by Mr. M. H. Hall.

Hydrogen or carbon monoxide is thus adsorbed on oxide surfaces in two distinct ways, one occurring at room temperatures, the process being reversible, and the other occurring at higher temperatures, which is irreversible. The reduction of oxides by either hydrogen or carbon monoxide therefore occurs in three stages, (1) the physical adsorption of hydrogen, (2) the chemical combination with the surface atoms, and (3) the desorption of water or carbon dioxide. It is curious that the physically-adsorbed gas must leave the surface before it can enter into chemical combination with the metallic oxides.

Capture of Electrons by α-Particles.

EXPERIMENTS, similar to those of Davis and Barnes (*Phys. Rev.*, **34**, 152, 1929; **35**, 217, 1930), have been made, in which a beam of α-particles passed through a stream of electrons, moving parallel to the α-particles. The apparatus differed from that of Davis and Barnes chiefly in that a Geiger counter, with mechanical recording system, was used in place of a scintillation screen, and that the polonium was inside the evacuated vessel. The number of singly-charged particles was always about one per cent of the total. The numbers of both doubly- and singly-charged particles were found to be entirely unaffected by the electron stream throughout the voltage range investigated, namely, from 450 to 750 volts. In particular, no capture was observed when the velocities of α-particles and electrons were nearly equal. Capture by the doubly-charged particles to an extent of less than 0·5 per cent would probably not have been detected, on account of probability error. N. A. de Bruyne was associated with me during part of this work.

Palæolithic Man in North-East Ireland.

THE series of Late Glacial and post-Glacial deposits reported upon by Dr. R. Lloyd Praeger from the Lagan estuary at Belfast [1] has been described as the most complete stratigraphical record of the post-Glacial sequence in the British Isles. The basal reassorted boulder clay was here overlain by grey sand with cold fauna, an early peat yielding *Cervus megaceros*, and superimposed estuarine clays, the lower of which has been elsewhere shown to have preceded the deposition of the well-known 25 ft. raised beach. We have recently found in such lower estuarine clay, in the neighbourhood of Larne, a derived but well-developed Magdalenian industry in flint. This industry will also be described by Mr. Burchell in his presidential address to the Prehistoric Society of East Anglia for 1931.

Science and Industry in Bristol.

By Engr. Capt. EDGAR C. SMITH, O.B.E., R.N.

NINETY-FOUR years ago the British Association, then but six years old, visited Bristol. After holding its first gathering at York in 1831, it had met at Oxford, Cambridge, Edinburgh, and Dublin, and then breaking away from the universities it came to a city the history of which is bound up with shipping, manufacture, and trade. Bristol to-day possesses its own university, with buildings which in beauty and dignity rival any to be found elsewhere, yet its geographical position and the energy and enterprise of its citizens have made it one of our chief commercial centres, and such it will probably remain. "The story of the trade of Bristol for a thousand years", said Mr. Baldwin when Prime Minister, "is the story of the trade of England", and at the recent summer meeting of the Institution of Mechanical Engineers the Lord Mayor and others referred with pride to Bristol's multiplicity of manufactures, volume of shipping, fine docks, air port, and municipal activities.

From very early times Bristol was a town of importance and a trading centre. When London had but 35,000 inhabitants, Bristol numbered 9000, and to-day it boasts of a population of some 400,000, the great majority of whom are connected with factories, warehouses, docks, and shipping. Declared by an early writer as a port fit and safe for a thousand ships, for the Siege of Calais Bristol provided Edward III. with 24 ships and 600 seamen; its Merchant Venturers stimulated both overseas commerce and exploration, and the noble memorial tower to the Cabots, erected in 1897, is a reminder of the famous voyage of the Bristol ship *Matthew*, which left the port on May 10, 1497, carrying the first Englishmen who ever saw the coast of North America.

If Bristol is a city concerned mainly with grain, fruit, sugar, chocolate, oil, and tobacco, with markets and commodities, it is nevertheless a city abounding in ecclesiastical, archæological, literary, and scientific associations. Few there are who go to Bristol who fail to visit St. Mary Redcliff, described by Leland as "by far the fairest of all churches", or recall the sad story of the unhappy poet Chatterton, whose boyhood was passed beneath its shadow. It was his strange work which brought Johnson and Boswell to Bristol, and led Johnson to remark, "This is the most extraordinary young man that has encountered my knowledge. It is wonderful how the whelp has written such things."

Scarcely less remarkable for his early achievements, but more fortunate in his environment than the Bristol attorney's apprentice, was the surgeon's apprentice from Penzance, Humphry Davy, who, still under the age of twenty, came to Bristol in 1798 to take charge of the laboratory at the Pneumatic Institution of Dr. Beddoes. A student of medicine in London and Edinburgh and sometime reader in chemistry at Oxford, Beddoes thought that the study of the physiological effects of different gases might have important therapeutic applications, and with this in view opened his hospital at Bristol. Known already to the Wedgwoods, to Gregory Watt, and to Davies Gilbert, through Gilbert, Davy joined Beddoes, and on Oct. 2, 1798, began work in the laboratory. If to the Bristol period of Davy's brilliant career belongs the publication of hastily conceived theories and ill-supported conclusions, to it also belongs the discovery of the effect on human beings of nitrous oxide. "A young man, a Mr. Davy, at Dr. Beddoes'," wrote Maria Edgeworth, "who has applied himself much to chemistry, has made some discoveries of importance, and enthusiastically expects wonders will be performed by the use of certain gases which inebriate in the most delightful manner, having the oblivious effects of Lethe, and at the same time giving the rapturous sensations of the Nectar of the Gods!"

At the time Davy was with Beddoes, and when he began his friendships with the Edgeworths and with Southey and Coleridge, the only means of reaching Bristol was by boat or horse or coach, and it was by these means that the members of the British Association came to the meeting of 1836, presided over by the Marquess of Lansdowne. From the north came Brewster, father of the Association, and J. D. Forbes; from Cambridge came Whewell; from London, Babbage, Wheatstone, Lardner, and Roget; and from Plymouth, Snow Harris. Brewster had spent a week with Fox Talbot at Lacock Abbey—"a paradise: a fine old abbey with the square of cloisters entire, fitted up as a residence, and its walls covered with ivy and ornamented with the finest evergreens"—now known to every student of the early history of photography. During the meeting Brewster stayed with "Mr. Daniells, Clifton", as also did the German geologist von Raumer. "The Bristol meeting went off extremely well", wrote J. D. Forbes from Edinburgh, to de la Rive, "and promises admirably for the permanency of the Association." For Forbes and his family, Bristol was to have other memories, for it was to the skill and attention of Dr. J. A. Symonds of Clifton he owed the prolongation of his life. To Symonds, whose house is now a hall of residence for women undergraduates, Forbes in after years sent the first copy of his *opus magnum*, his valuable historical review of the progress of physical science from 1775 to 1850, contained in the 8th edition of the "Encyclopædia Britannica". It was at Clifton, too, that Forbes on the last day of 1868 breathed his last.

If travellers in 1836 had still to submit to the discomforts of the mail coach, they were all acquainted with the progress of the new railways, and no visitor to Bristol could have failed to hear of Brunel, then engaged on the construction of the line from Bristol to London. Brunel with Locke and Robert Stephenson formed the triumvirate of the early railway world, and Brunel's finest monument is the Great Western Railway. A Bristol and London Railroad Company had been formed in the Bristol Guildhall on July 30, 1833, and two

years later Brunel wrote: "I am thus engineer to the finest work in England. A handsome salary, on excellent terms with my directors, and all going smoothly." Opened as far as Maidenhead in 1838, the line was extended to Reading early in 1840, Bristol and Bath were joined in August of the same year, and Bristol and London in June 1841. When next the British Association met in Bristol no fewer than 17,000 miles of railroad had been laid down in the kingdom, and Brunel's bridges and viaducts were the admiration of the world.

Brunel's association with Bristol did not end, however, with the railway. The line from London to Bristol had given birth in his remarkable mind to the idea of a steamship to connect Bristol with New York, and on the banks of the Avon in 1836 was laid the keel of the most famous and most successful of all early trans-Atlantic liners. Designed by Brunel, built by Patterson, and engined by Maudslay of London, the *Great Western* was 236 ft. long, 2300 tons displacement, and 750 horse-power. She left Bristol on her maiden voyage, on April 8, 1838, crossed to New York in fifteen days, and before she was sold in 1846 she had crossed and recrossed 74 times. What George Stephenson's Liverpool and Manchester line of 1830 had been to the railway so the *Great Western* was to trans-Atlantic steam navigation. Neither must it be forgotten that Brunel's *Great Britain*, the first screw ship to cross the Atlantic, was also built at Bristol.

Just as the builders of railways had to fight opposition and disarm criticism, so the promoters of the Atlantic steamships had to face scepticism, and the British Association meeting of 1836 gained a certain notoriety through the public lecture of Lardner, then professor of natural philosophy and astronomy in University College, London, and the recognised and popular exponent of science. Lardner in his lecture saw fit to sound a note of caution regarding the scheme for trans-Atlantic steam navigation, but himself incautiously spoke of it as chimerical. The storm of protest which broke upon his head was more or less deserved, but the letters of Macgregor Laird and others were not half so effectual a reply as the fine performances of the *Great Western*.

Brunel had first become known in Bristol through his plans for a bridge to span the Avon at Clifton. His were not the only plans and Brunel did not live to see the bridge erected, but when in 1864 the fine suspension bridge was opened, incorporated with it were the chains from the old Hungerford footbridge over the Thames at London, built by Brunel in the 'forties, but which had had to make room for Hawkshaw's Charing Cross Bridge. The responsibility for the Clifton Bridge we see to-day was shared by Hawkshaw and Barlow, and it was Hawkshaw who in 1875 came to Bristol to preside over the British Association on the occasion of its second visit to the city.

By 1875 the British Association had become a great national institution, having long achieved that permanency Forbes hoped for, while the names of Huxley, Darwin, Tyndall, and Thomson were on everybody's lips. Serving many causes, it had especially promoted the spread of knowledge, and its second visit to Bristol took place just before the birth of the college which was founded in 1876 and from which has sprung the university which is to-day one of the glories of the city. With an ancient grammar school, and the newly founded Clifton College within its boundaries, Bristol in the early 'seventies was still without the means for higher instruction. But following the lead of London, Newcastle, Manchester, North Wales, and Leeds, and supported by Balliol and New College, Oxford, Bristol on June 11, 1874, at the Victoria Rooms, Clifton, launched the scheme for a college of university rank. Backed by the great influence of Jowett and of Percival, then headmaster of Clifton College, the scheme was further discussed at a meeting in August 1875, while the British Association was in session, and in 1876 the college began its work.

The first lectures of the college were given in a dilapidated old house in Park Row, at the top of Park Street; the first professor of chemistry was Letts; the first principal, the economist Alfred Marshall. The removal of Letts to Belfast and of Marshall to Cambridge opened the path for Ramsay, who at the age of thirty had already made his mark, and under him and his colleagues—Lloyd Morgan (who succeeded him as principal), Orme Masson, Sydney Young, Silvanus Thompson, Sollas, Hele Shaw, and others—the college soon attained to a leading position among the provincial centres of learning and research, and in 1909 it was raised to the dignity of a university. In St. Mary's Redcliff is a window to "the pious memory of men who made Bristol famous in the fourteenth and fifteenth centuries". No such memorial will be necessary for the men who have made Bristol famous in our own day: for their energy, enterprise, foresight, and munificence have already raised an enduring monument in the splendid range of university buildings, associated particularly with the name of the Wills family, which stands at the top of Park Street, where was once the house which sheltered its earliest professors and students.

The connexion of industry and science with Bristol might well be illustrated by references to many other men, places, and events. More than two hundred years ago, the famous Abraham Darby, before removing to Coalbrookdale, founded in Bristol the Baptist Mills Brass Works, where, with the aid of Dutch workmen, he endeavoured to meet a need of the times by casting iron pots in moulds of sand to take the place of the more expensive brass pots; while to Peregrine Phillips, Jr., a Bristol vinegar maker—of whom Sir Ernest Cook wrote in NATURE of Mar. 26, 1926, p. 419—we owe the invention of the contact process for the manufacture of sulphuric acid. Though the particulars of his invention are fully known, it is otherwise with the career of Phillips, details of whose life have escaped both the historians of chemistry and biographers. In our own time there have been few who have furthered the interests of science in

No. 3175 SEPTEMBER 6, 1930

Size and Form in Plants.

By Prof. F. O. BOWER, F.R.S., President of the British Association.

INAUGURAL ADDRESS DELIVERED AT BRISTOL ON SEPT. 3.

TWO years have passed since the British Association last met in Britain. Events have happened in that interval which mark the close of the Darwinian epoch. Down House, in which Darwin lived and worked, has been bought, restored, and endowed by Mr. Buckston Browne and presented by him to the Association, which holds it in custody for the nation. The house is now open as a shrine to those who treasure Darwin's memory. They may enter the study where the "Origin of Species" was penned, or wander out to the Sand Walk, and draw such inspiration as those spots may yet afford to those who are face to face with problems cognate to his own. These years have also severed personal links with Darwin himself. Sir William Thiselton-Dyer, who died in December 1928, had been his frequent correspondent. It was he who, more than any other, carried the evolutionary stimulus forward into the botanical schools of Britain. Sir Edwin Ray Lankester, whose portrait by Orpen was a poignant feature of last year's Academy, died in August 1929. Not only was he the leading zoologist of his time, but he has left a deep impress on general morphology; for he was the first to analyse from the evolutionary aspect the degrees of 'sameness' of parts, whether in animals or in plants. These two octogenarians were among the latest links between Darwin himself and living men of science; so this last meeting of the Association before its centenary next year falls at a nodal point in the personal history of evolution.

Morphology, or the study of form, was closely interwoven with the life's work of Darwin, and—to use his own words—"it is one of the most interesting departments of natural history, and may almost be said to be its very soul". Since the Association has seen fit to choose as this year's president a botanist whose work has dealt specially with form in plants, the occasion seems apt for considering certain morphological questions that present themselves in this eighth decade since the "Origin of Species" was published.

The word 'morphology' was applied by Goethe in 1817, in a general sense, to the study of form. Though a pre-Darwinian, he showed rare foresight in insisting that the living form is only momentarily stable, never permanent. But years elapsed before that instability of form of living things, which he clearly saw, became the very focus of evolutionary theory. Even Goethe's prophetic gaze was blurred by the hazy imaginings of idealistic philosophy. The clarifying mind of Schleiden resolved that mist by resort to naked fact. In 1845 he stoutly asserted that the history of development is the true foundation for all insight into living form. This opened the way for a host of workers, who patiently observed and compared the facts of individual development, particularly in plants of low organisation. By them the field was prepared for the magic touch of Darwin; and, in the enthusiastic words of Sachs, "the theory of descent had only to accept what genetic morphology had actually brought to view".

The effect of that theory should have been to sweep aside all idealistic morphology based on the higher forms, and to rivet attention upon organisms low in the scale. It was the habit of starting comparison from the highest state of organisation that was the fundamental error of the idealistic

Nature-philosophers; even now traces of it still persist. An illuminating alternative was presented by that noble passage with which the "Origin of Species" ends. Speaking of his theory, Darwin wrote: "There is a grandeur in this view of life, with its several powers, having been originally breathed by the Creator into a few forms, or into one; and that—from so simple a beginning endless forms most beautiful and most wonderful have been, and are being evolved." He forecast from the application of his theory that "our classifications will come to be, as far as they can be so made, genealogies; and they will then truly give what may be called the plan of creation".

Whether there was only one original form of life or many is still an open question. Nevertheless, among the welter of organisms rightly held as primitive, the Flagellata may with some degree of reason be named as combining in their motile and sedentary stages respectively the animal and vegetable characters. They suggest a sort of starting-point from which the two kingdoms might have diverged. The probability of their common origin is strong; but the divergence must have been early, each taking its own independent course, with increasing size and complexity of the individual. In tracing this I would ask special attention to the kingdom of plants.

The first of the laws laid down by Lamarck in his "Histoire Naturelle" as fundamental in the evolution of animals and plants ran thus: "Life by its intrinsic forces tends to increase the volume of every living body, and to enlarge its parts up to a limit which it determines itself." When in unicellular organisms, following this law, a certain size has been reached, fission follows, and the equal halves separate as new individuals. In pluricellular bodies, however, the products of cell-division do not separate, but continue a communal life; and the individual may increase, with further division of its cells, to large size and complexity. We may picture how, based upon the mobile stage of a Flagellate, the aggregate might form an animal body with motility as a leading feature; on the other hand, based upon the sedentary stage, an immobile plant body would result. The animal, adopting a predatory habit and colourless, might progress along lines of dependent nutrition, finding and ingesting food already organised; the sedentary green plant might evolve along lines of physiological independence, constructing its own organic supplies. Whether or not this be a true picture, the whole organisation of the two kingdoms diverged on the basis of nutrition. Herbert Spencer contrasted them physiologically, showing how animals are expenders, while plants are accumulators; that the former are limited in their growth by the balance of expenditure against nutrition; in the latter, growth is not so limited. Thus the problems that follow on increasing size may be expected to work out differently in view of the animal kingdom comprising organisms of high expenditure and not self-nourishing, while plants are self-nourishing accumulators.

The result of this difference may be illustrated by contrasting some of the highest examples of either kingdom: for example, the elephant with the trees of the forest through which he roams; on one hand, the relative fewness of the mobile elephants, their less stature and compact form, their columnar legs needed to support the barrel-like body, the receptacle for ingested food, the economy of external surface and the highly developed internal surfaces; on the other hand, the height, immobility, and large number of the trees, with their massive stems and highly complex shoots and roots, so necessary for acquiring food directly from the air and soil. We may further contrast the genesis of the individual in either case. In the mammal the parts are formed once for all, its embryology being an incident closed early in the individual life; but in the tree, embryology may be continued for centuries, and is theoretically unlimited, except by death; during life it has the power of producing leaves and branches from every distal bud. The fact is that, though certain underlying principles are the same for both kingdoms, the working out has been distinct from the first. Hence the morphology of plants must stand on its own feet; indeed, it has been said with some degree of truth that whenever botanists have borrowed their morphological outlook from the sister science they have gone wrong.

The normal development of a multicellular plant starts from the fertilised egg, and elaboration both external and internal follows on increasing size. Polarity, that is the distinction of apex and base, is defined in most plants of high organisation by the first cell-cleavage. The apex adopts at once the continued development that is its characteristic. Branching of various types follows in all but the simplest, to constitute the complex shoot, while correlative basal branching gives the root-system that fixes the non-motile body in the soil. The scheme of growth and branching thus started is theoretically open to unlimited increase, and the initiation of new parts is in point of number on a geometrical scale. This

is suitable enough for organisms able to accumulate material, as plants do; indeed, the elaboration of the vegetative system will enhance its powers of self-nutrition, so far as the parts become functional; but this is never fully realised beyond the earlier steps.

The focus of all such development is the growing point, respectively of root or shoot. Anyone who carefully dissects a suitable bud, peeling off the successively smaller leaves, may finally see with the naked eye or with a simple lens a pearly cone of semi-transparent tissue at the tip of the stem. This is the growing point itself, which possesses theoretically unlimited formative power. It is like a permanent sector of the original embryo that is fed continually from the mature tissues below, and as continually forms fresh tissues at the tip. But as the tip advances, lateral swellings of the surface appear in due order, which are new leaves and buds. Various attempts have been made to link the genesis of these outgrowths of the radial shoot with the outer world as regards their position and number. But we have it as the latest authoritative statement on this point that such a relation does not exist. " This much is proved," says Prof. von Goebel, that, " so far as we can see, the question relates to conditions of growth and symmetry that arise in the growing point. All theories as to leaf-position that allotted a passive rôle to the growing point were mistaken, however acute the reasoning that was brought to bear thereon" ("Organographie", 3rd ed., part I., pp. 299-300). This is Von Goebel's summing up for external parts. On the other hand, within the growing point, and often, though not always, related to the external parts, there is a progressive formation of internal conducting tracts, continuous from the adult region upwards to the tip. A like reference of the origin and disposition of these vascular tracts to the growing point itself appears to be equally justified. In fact, the tip possesses the initiative for both.

The complex shoot that results from such initiation is exposed as it matures to external conditions which modify its form. Their effect is very obvious in the young shoot of the higher plants. As the shoot elongates, its young tissues are soft and plastic. While in this state its form may be influenced by gravity, the incidence of light, mechanical contact, and other causes which produce reactions of form called 'tropisms'. All of these promote the well-being of the whole. The net result becomes fixed as the part matures, and its constituent tissues harden. Thus the adult form is the consequence of the primary initiation at the growing point, modified by the conditions to which the plant may have been exposed during the plastic period. This is a commonplace of the text-books. But amid all the careful analysis and experiment that has been devoted to the influences which thus affect form, one factor, insistent and unavoidable, has been habitually left out, namely, the influence of size. Reference is occasionally made in text-books to the effect of surface tension in determining the simple form in minute organisms, such as unicellular Algæ and Bacteria; and to the deviations from that simple form as the size increases, and the influence of surface tension ceases to be dominant. At the other end of the scale of size, mathematicians have calculated the extreme stature mechanically possible for a tree-trunk constructed after the ordinary plan, and of materials of known strength. The result is about 300 feet, and this coincides approximately with the limit of height of the canopy of a tropical forest. But in point of size practically the whole of the vegetable kingdom lies between the microbe and the forest tree. Unfortunately, the study of these middle terms, from the point of view of change of form as the size increases, has not been pursued by botanists with the same perception as zoologists have shown in the study of animals.

At the back of all problems raised by increasing size stands the well-known principle of similarity, which applies to all structures, inorganic as well as organic. It involves among other consequences that where form remains unaltered bulk increases as the cube, but surface only as the square of the linear dimensions. But in living organisms it is through the limiting surfaces, or 'presentation-surfaces', as they are called, that physiological interchange is effected. Provided a surface be continuous and its character uniform, it may be assumed that such interchange will be proportional to the area of surface involved. If, then, the form of the growing organism or tissue were retained as at first—for example, a simple sphere, oval, or cylinder—its surfaces of transit would increase at a lower ratio than the bulk which they enclose. There would be with increase in size a constantly decreasing proportion of surface to bulk, and as constantly an approach to a point of physiological inefficiency. But any change from a simpler to a more complex form would tend to uphold the proportion of presentation-surface. Thus the success of a growing organism might be promoted by elaboration of form. Naturally, other factors than that of size co-operate in determining form.

Nevertheless, the recognition of such elaborations of form, whether external or internal, as do tend in point of fact to maintain a due proportion of surface to bulk as growth proceeds, should help to make morphology a rational study. The diffuse form habitual for plants, even the origin of leaves themselves, becomes intelligible from this point of view.

In the construction of any ordinary vascular plant there are three of these 'presentation-surfaces' or limiting surfaces of transit, that are of prime importance: (i) The outer contour by which it faces the surrounding medium; (ii) the sheath of endodermis which envelops the primary conducting tracts; and (iii) that collective surface by which the dead woody elements face upon the living cells that embed them, through which water and solutes pass in or out. Each of these may vary independently of the others, and each would be a fitting subject for observation as bearing on this problem of size. But as a test case of the relation between size and form, it is the collective surface where dead wood faces on living cells that will meet our requirements best, for its study can be pursued among fossils almost as well as in living plants. The problem is one not merely of current physiology of the higher plants: it is one of adaptive progress. Accordingly, measurements must be made of the wood of fossils as well as of living plants, and of young sporelings as well as of the adult.

We have seen that plants are essentially accumulators of material. A natural consequence of this is that primitive types, endowed with apical growth but with no secondary cambium, will enlarge from the base upwards. Any sporeling fern shows this. The leaves themselves increase in number; each successive leaf is as a rule larger than the one that came before, and the stem that bears them also expands upwards. In fact, it takes the form of an inverted cone. To grasp the size problem for primitive plants the mind must be rid of the idea of the forest tree, with its stem tapering upwards, for that is a state of highly advanced organisation. The primitive form of stem is that of an inverted cone, enlarging upwards, with a solid core of wood within. A cone standing upon its tip is obviously unpractical. Not only is it mechanically unstable, but if the original structure be maintained so that the larger region above is structurally a mere magnified image of the smaller below, a constantly diminishing proportion of presentation-area to bulk must needs follow, in respect of all the limiting surfaces. Such stems would all tend to become physiologically insufficient. Our immediate problem is with the woody column. How can that due proportion of presentation-surface of the dead wood to the living cells, which physiologists hold to be essential, be maintained in the expanding stem, so as to meet the increasing requirements of transit and distribution of the sap?

This is not the place for a recital of the details of elaboration of the wood which have been observed and measured. It must suffice to state in general terms how primitive woody plants have met the difficulty in the absence of cambial thickening. The starting-point is a minute cylindrical strand composed of dead tracheids only. Some primitive types show nothing more than a conical enlargement of this upwards, with the cells more numerous than before. The approach of a locomotive at speed along a straight track may visually suggest such increase in size without change of form; successive photographs of it might be compared with successive sections of those simple stems enlarging upwards without change of plan. The largest examples of this are found in some of the early club mosses and ferns, in which there is an enlarging solid woody core. But for want of resource in this and other features they have paid the penalty of death. Most plants having this crude structure are known only as fossils, and no really large vascular plant lives to-day which shows it. Under present conditions, it is only where the size is small that a simple mass of dead tracheids seems to be effective for water transit. Thus we see that simple enlargement without change of form does not suffice.

In more resourceful plants a remedy is found in elaboration of the form and constitution of the primary wood. The changes which actually appear in it, as the size of the individual or of the race increases, are very various, but they all tend towards making the wood a living whole. The most efficient state would be that in which each dead woody cell or element faces upon one or more living cells, and this structure is approached in modern types of wood. In tracing the steps which have led towards it, whether in the fossil story or in the individual life of plants, we follow up an evolutionary history of high functional import. Actual measurements and calculations have shown in living plants the advantage that follows. It has been found that changes in the elaboration of form and structure of the primary woody column have saved, in specific instances, about 50 per cent of the contingent loss in that proportion of presentation-surface to living tissue which would

have followed if a simple cylindrical core had been retained. The structural changes do not, it is true, maintain the full original ratio of surface to bulk, but it may well be that saving even half of the contingent loss would bridge the acute risk and lead to survival.

The moulding and subdivision of the primary conducting tracts as a whole, or of the woody masses which they contain, present the most varied features. Their contours often appear arbitrary and even irrational, so long as no underlying principle is apprehended. They have presented a standing problem to anatomists. But when it is realised that as the size increases there is a physiological advantage in any elaboration of form whatsoever, a rational explanation is at hand. The variety of the forms assumed suggests the common principle underlying them all, which is that thereby a due proportion of presentation-surface tends to be maintained.

One of the simplest and most frequent examples of such elaboration of form is that of the fluted column, which in transverse section gives the familiar stellate figure characteristic of roots. It is also seen in many stems, and is described as 'radial'. Where the part is small the woody strand is roughly cylindrical, but where larger it often becomes fluted, with varying number and depth of the flanges. In many instances the ratio of their number to the diameter of the whole tract is approximately constant. The structure is in fact adjusted to the size. This is so in roots generally, in leafy stems, and in leafless rhizomes—and a similar size relation is even found in the fluted chloroplasts of certain Algæ. In all of these an obvious risk following an increase in size tends to be eliminated, namely, an undue loss of proportion of surface to bulk.

The somewhat technical facts thus briefly described may be taken as examples of a relation of form to size which is very general. They suggest the existence of a 'size factor', which is effective in determining form. The susceptibility to its influence resides in the part that shows the results. The internal contours are defined *ab initio*, instead of coming into existence during the course of development, as is the case with the convolutions of the mammalian brain. In the stem and roots of vascular plants the fully matured conducting tracts may be traced upwards, with their outlines already defined, through successive stages of youth towards the growing point, which has been their source. Their form may be seen already outlined in its young tissue closely short of the extreme tip. This fact suggests that the susceptibility to the size factor resides in the growing point itself, for immediately below it those tracts possess that form which will aid their function when they are fully developed.

Of all the factors that contribute to the determination of form in growing organisms, there is none so constant and inevitable in its incidence as this size relation. Its operation becomes manifest with the very first signs of differentiation of the embryonic tissues. The effects of other factors that influence form, such as gravity, light, temperature, contact, and the rest, appear later in point of time. Their influence is liable to diminish as the organism reacts to them by curvature or otherwise, and to vanish when the reaction is completed. Under experiment they may be controlled or even inhibited. But the operation of the size factor is insistent; it cannot be avoided either under conditions of Nature or by experiment, though the size itself may be varied under conditions of nutrition, and the permeability of the presentation-surfaces may not be constant, with results as yet unknown. When we reflect that all acquisition of nourishment and transit of material in plants of primary construction is carried out through limiting surfaces, the essential importance of the size factor is evident, for upon its influence the proportion of each presentation-surface itself depends.

The evidence that size itself is, among other factors, a determinant of form rests upon the constancy with which, in an enlarging organism, changes of primary form tend to maintain a due area of presentation-surface such as active transit demands. That evidence has been derived chiefly from the conducting tracts of primary individuals as they enlarge conically upwards, and from parts belonging to distinct categories, also from comparison of different individuals not necessarily of close alliance. Very cogent evidence lies in the variety of the changes of form by which the same end is attained. Finally, the converse facts bring conviction when, as often happens, a distal diminution of size in stem or leaf is accompanied by simplification along lines roughly the converse of those that follow increase.

All this shows that a real relation exists between size and primary form. The term 'size factor' has been used to connote that influence which affects form in relation to size, but without defining it except by its results. Nevertheless, we have seen that its action may be located in near proximity to the growing point, or in the embryo itself.

It has not, however, been found possible to assign to that effect an immediate cause. The attitude thus adopted towards an undoubted factor seems justified by the broad logic of science, and by the practice of its highest votaries. When Newton put together his great physical synthesis, he pointed out at the close of the "Principia" that the cause of gravitational force was unknown. "Hitherto I have not been able to discover", he said, "the cause of these properties of gravity from phænomena, and I frame no hypotheses." Likewise, in its own more restricted field of botanical phenomena, the size factor may be recognised as effective in development, though the immediate cause of its effectiveness is still unknown.

The position thus adopted assumes the shoot to be a unit, not a congeries of 'phytons'. The elaboration of its form, whether external or internal, would be a function of the increase in size of that unit, and the result would tend to maintain the adequacy of the presentation-surfaces. This conception of the shoot and of its parts would accord with the views of General Smuts, as stated in his remarkable work on "Holism", published in 1926. Many who heard his address in Cape Town last year, when opening the discussion on "The Nature of Life", will value this masterly statement in brief of his theory. I suggest that the operation of the size factor, whether in relation to external leaf-development or in the elaboration of internal conducting tracts, illustrates that "measure of self-direction" ascribed by him to every living organism ("Holism", p. 98).

The discussion of the problem of size and form in plants, which has occupied our attention thus far, raises questions of profound significance in the sphere of pure botany. There is, however, another interest inherent in the study of plants beyond that of pure science. I mean botany as applied to the needs of man. To-day this touches human life more closely than ever before. Every meal we eat, many of the clothes we wear, timber, rubber, a whole volume in itself; the drugs, narcotics, dyes, and scents, and most of that vast tale of accessories that ameliorate life, depend for their supply, quality, and often for their existence upon the skilled work of the botanical expert. He is trained in our schools and universities. His experience there is perfected by work on farms and plantations, in forests and in factories, often by adventurous life abroad. It would be superfluous for me to enter into detail on such matters, for happily the Director of Kew presides over the Botanical Section, and he can speak with the fullest knowledge on the application of botanical science to modern life.

Government departments are now linked more closely than ever with universities and technical colleges by the golden chain of grants. The botanical institutes that have sprung from this joint source are mostly focused at such centres as Kew and South Kensington, Cambridge and Oxford, Harpenden and Merton, Long Ashton and Corstorphine, Plymouth and Millport, with important outliers such as Dehra Dun in India, the Imperial College of Tropical Agriculture in Trinidad, and the Research Station at Amani, East Africa; while similar stations are to be found in Canada, at the Cape, in Australia and New Zealand. Their activities are as diverse as their position. Agriculture, forestry, plant-breeding and distribution, seed-testing, mycology, and plant pathology—these are but a few of the headings under which applied botany is now pursued; and a duly qualified staff is required for each. Kew itself, thanks to the foresight of the Empire Marketing Board, is developing ever more and more as a co-ordinating centre for the whole Empire. Highly specialised study such as this has sprung into existence in the last half-century. As regards Britain, its origin may be traced to the biological laboratory of the old Normal School of Science at South Kensington, where biological research was revived under Huxley and Thiselton-Dyer.

The first botanist there trained in pure science who turned the newly acquired vision to practical account in the interests of the Empire was Marshall Ward. For two years he investigated the coffee disease that had half ruined Ceylon. It is a long step from this individual effort in the East to the firmly established and efficient Imperial Mycological Bureau, recently housed at Kew in a new building devoted to the world-wide study of the fungal diseases of plants. Such advance along a single line of applied botany may be taken as an index of the progress from simple beginnings in pure botany to that widespread attack now being made upon the economic problems that face Imperial agriculture. The history of it thus briefly suggested may be read as a parable, showing how natural is the progression from the study of pure science to its practical application. For there is no real distinction between pure and applied science. As Huxley told us long ago, "What people call applied science is nothing but the application of pure science to particular problems".

At the moment there is an unprecedented demand for botanical specialists to fill investigational

and advisory posts at home and abroad, and there is a shortage of applicants. The realisation of this will doubtless be transmitted through the universities and colleges to the schools of the country, and lead to an increased supply. On the other hand, it lies with the Government to react as other markets do in taking steps to equalise supply and demand. A condition of the success of a specialist will always be a thorough foundation upon pure science, and this will be fully realised in the selection of candidates. Government, whether at home or in the wider Imperial field, can make no better investment than by the engagement of the best scientific experts available. In respect of botany this has been attested by many well-known instances.

Some reference will naturally be expected here to the remarkable address given by Sir William Crookes in 1898, when the Association last met in Bristol. He then forecast that, in view of the increase in unit-consumption since 1871 and the low average of acre-yield, "wheat cannot long retain its dominant position among the foodstuffs of the civilised world. The details of the impending catastrophe no one can predict, but its general direction is obvious enough. Should all the wheat-growing countries add to their area to the utmost capacity, on the most careful calculation the yield would give us . . . just enough to supply the increase of population among bread-eaters till the year 1931." The problem is one of applied botany, with a setting of world economics and a core of physical chemistry. After raising the spectre of wheat shortage before the eyes of his audience of 1898, Crookes laid it again by the comforting words, "The future can take care of itself. The artificial production of nitrate is clearly within view, and by its aid the land devoted to wheat can be brought up to the 30 bushels per acre standard." We who are living within a few months of the fateful year of 1931 are unaware of any wheat shortage. Sir William Crookes's forecast of 1898 as to the advance in the production of combined nitrogen has been fully realised. Artificial fertilisers are not in view only, but at hand and in mass. Moreover, the northern limit of successful wheat culture has been greatly extended by the production of new strains with ever shortening period between sowing and reaping, while the establishment of new varieties is extending the productive area in South and West Australia into regions where the rainfall is of short duration, and restricted in amount.

The future, since 1898, has indeed taken care of itself; so that, notwithstanding the warning of so great a man as Sir William Crookes, the wheat-eating public is still able to sleep well at night so far as the wheat shortage is concerned. What better example than this could we desire, not only of the importance of applied botany, but as showing also how its advance follows on research independently pursued? For the production of synthetic nitrogen, which has now become a commercial proposition, and the improvement of the strains of wheat by selective breeding along Mendelian lines, are both involved in solving this crucial question of food-supply; and both owe their origin to advances in pure science.

In conclusion, we shall all be conscious of the fact that a most distinguished former president of the Association has lately passed away, one who more than any man has influenced the policy of government in relation to science. I mean Lord Balfour. We recall how in 1904 he, so thoroughly imbued with the spirit of his *Alma Mater*, presided over the meeting in Cambridge. He was distinguished as a philosopher, great as a statesman, and particularly so under the stress of war. He it was who, after peace returned, used his rare influence in transforming the war-time experiment of a committee of the Privy Council for Scientific and Industrial Research into a permanent and essential part of modern government. But this was not all. His critical, constructive, and experienced mind was led to formulate a still wider plan. A Cabinet Committee for Civil Research was to be established on the lines of the Imperial Defence Committee. He designed it so as to bring the whole national administration within the range of scientific influence. The Department of Scientific and Industrial Research, so wisely kept in being after 1919, now forms part of that larger scheme. This department is responsible for making recommendations as to the expenditure of funds voted by Parliament for research, especially in relation to industry. Thus science is welcomed into the inner circle of Imperial administration. This the State owes to Lord Balfour.

And so in this hundredth year of its existence, the British Association sees research recognised and fostered in the service of the State in a way never dreamed of in 1831, when a small body of enthusiasts met at York for the advancement of science. But though the individual seeker after truth may thus be involved in official harness, as of old an inner voice will yet speak to him. He will himself be as near to Nature to-day as he was in the simpler days that are gone.

Summaries of Addresses of Presidents of Sections.*

Terrestrial Magnetism.

THE subject of Dr. F. E. Smith's presidential address to Section A (Mathematical and Physical Science) is "Theories of Terrestrial Magnetism". He begins by referring to early magnetic conferences and resolutions urging international co-operation, but while believing the spirit of international co-operation in terrestrial magnetism to be excellent, the question is put: "Do we make our plans sufficiently well?" While it is to the International Union of Geodesy and Geophysics that we must look to plan lines of attack, Dr. Smith makes a plea for the adoption by many of the first class magnetic observatories of a programme including observations at the same time and with similar instruments of great sensitivity. Later in the address, when the question of simultaneity of magnetic storms is considered, this plea for similar instruments is revived, and the opinion is expressed that it should not be difficult to obtain a decisive answer to such a question by proper organisation. A point emphasised is that while each observatory should have its own particular problems and its own special methods of attacking them, and thus preserve its individuality, it should in addition have part of its equipment of an international type and part of its programme truly international in character.

The general character of the earth's magnetic field is described, theories relating to the permanent field being considered first. Our knowledge respecting changes in the permanent field is very limited, the secular variation being the only one of which we have trustworthy data. Schuster put forward the theory that the secular change is caused by the magnetic field inducing currents in an outer conducting medium not moving with the earth, or moving relatively to it. It is pointed out that it is not necessary to assume a large volume of outer space to have uniform conductivity to produce the effect. An outer layer will suffice and the conductivity may be uniform or patchy. The irregularities in the secular change are possibly due to the conductivity of the layer varying over considerable areas, and the relative motion between the earth and portions of the layer may also vary.

The question of electric currents circulating round the earth is next dealt with, a possible source of the electromotive force being due, as Larmor has suggested, to the existence of a residual internal circulation in meridian planes, which, cutting such a magnetic field as that of the earth, acts as a self-exciting dynamo. Another theory due to Gunn is that the inner earth has a temperature of the order of 1000°, and that it is highly ionised and a good conductor. A primary current system is supposed to be set up from the motions imposed upon ions by the internal gravitational electric field at right angles to the magnetic field, the action being a regenerative one.

The possibility of the magnetic field being due to the earth's rotation is fully considered, the associated effects of surface charge, volume charge, and gyromagnetic action being dealt with in turn. Owing to so many difficulties presenting themselves when the theories are analysed, modifications of the laws of electrodynamics have been suggested, but the theories are not satisfactory. Dr. Smith concludes that our knowledge of the cause of the earth's magnetic field is little more than conjectural, for, of the theories put forward, all that have been put to a practical test have been found wanting in some respect.

Dr. Smith then discusses vertical electric currents; while Bauer was justified in drawing his conclusions as to the existence and magnitude of such currents, the data he used are not sufficiently trustworthy. The existence of the currents is exceedingly doubtful, but sufficiently precise measurements could be made over a carefully chosen area, which would enable a definite decision to be reached.

Three theories of diurnal variation are dealt with: the 'dynamo theory', in which conducting layers of air cut the earth's permanent field and so induce electric currents; the 'diamagnetic theory', in which a diamagnetic layer is formed by ionisation, the shape of the layer being that of a hemispherical cap; and the 'drift current theory', which depends on the drift of ions and electrons in the diamagnetic layer. A direct effect of the diamagnetic layer is considered to be certain, but with it is associated an effect due to the drift currents which is much larger, and the direct effect of the diamagnetic layer is therefore considered to be of secondary importance. The dynamo theory is favoured less than the drift current theory. The other variations considered are those due to solar eclipses and magnetic storms.

The address concludes with a plea for the pro-

* The collected presidential addresses delivered at Bristol are published under the title "The Advancement of Science, 1930". The volume is obtainable at 5*s*. of all booksellers, or at the Reception Room, Bristol, by members attending the meeting, 3*s*. 6*d*.

duction of data of a more precise kind, the final paragraph quoting a passage from Rücker's address in Bristol in 1898, which emphasises the need for more perfect organisation.

A State Experiment in Chemical Research.

The subject of Prof. G. T. Morgan's address to Section B (Chemistry) is the Chemical Research Laboratory at Teddington which was originated about five years ago by the Department of Scientific and Industrial Research in order to bring together scattered groups of research workers who were then engaged in various localities on chemical investigations of national importance. The site selected on the Bushy Park Estate in close proximity to the National Physical Laboratory allows of ample scope for future expansion. Three laboratory units were contemplated originally, and after five years rather more than one half-unit has been completed and occupied.

A Chemistry Research Board advises the Department on the programme of research and exercises general supervision over its execution. Six investigations have been prescribed at various times, and are described by Prof. Morgan in the order in which they have come under his notice.

1. Synthetic resins, employed in the manufacture of moulding powders, electric components, and shellac substitutes are of growing importance in chemical industry, and since May 1925 an investigation on the production of resins from formaldehyde and the cresols and xylenols has been in progress. Resins of high dielectric capacity have been obtained and fresh information has been gained concerning the chemistry of these condensations.

2. In collaboration with H.M. Fuel Research Station a systematic study has been made of the chemical constituents of the tar derived from low temperature carbonisation. The isolation from this and other tars of four chemical groups of resins is an outstanding result of this research, which has also led to the characterisation of several methyl derivatives of anthracene contained in the less volatile oils of low temperature tar.

3. An investigation, involving a concerted effort by chemist and chemical engineer, has been initiated on the use of pressure in facilitating chemical reactions. By the interaction of carbon monoxide and hydrogen in contact with various catalysts at high temperatures and pressures, many members of the homologous series of alcohols, aldehydes, fatty acids, and esters have been synthesised. Methyl alcohol remains the predominant product, but ethyl alcohol has appeared to a not inconsiderable extent.

4. The corrosion of metals either in air or when immersed in water or salt solutions is of interest to the metallurgist and industrial chemist. Both these aspects of corrosion are under examination at Teddington. A quantitative study of immersed metals shows that their corrosion is not inherently erratic but controllable and quite a suitable subject for physico-chemical investigation.

Two noteworthy discoveries have been made during these researches in regard to the composition of the green patina which develops on exposed copper surfaces. Contrary to the belief of the last 100 years this corrosion product, as developed in England, is not basic copper carbonate but consists mainly of basic copper sulphate, the carbonate, if present at all, being only a minor constituent of the patina. Under marine conditions the basic sulphate becomes more or less replaced by basic copper chloride. Moreover, in patinas of at least 70 years' growth the composition of the basic sulphate corresponds with that of the mineral, brochantite, $CuSO_4,3Cu(OH)_2$. Similarly the marine patinas tend towards the composition of atacamite $CuCl_2$, $3Cu(OH)_2$.

5. In collaboration with the Chemotherapy Committee of the Medical Research Council a group of workers is engaged in the preparation of organic compounds of therapeutic interest. Analogues of Bayer 205 or Fourneau 309 have been submitted to the Committee together with many organic derivations of arsenic and antimony. So far the organometallic series has furnished the more promising results as regards trypanocidal activity.

6. During the last two years experiments have been in progress under the auspices of the Water Pollution Research Board on the base-exchange (zeolite) method of water softening. One objection raised against this process is that the water might become contaminated with silica and alumina arising from the disintegration of base-exchange material. Experiments have shown, however, that this fear is groundless; the silica content is not increased seriously and is not greater than that often encountered in untreated waters. Along with these practical tests, a report summarising existing knowledge of zeolite water softening has been compiled and published.

In addition to the foregoing prescribed investigations a certain amount of general research has been carried out on complex aromatic hydrocarbons including acenaphthene and diphenyl, waxes and higher fatty acids, cyclic systems containing

selenium and allurium, and co-ordination compounds of copper, silver, and gold.

The address is fully illustrated by an exhibit of preparations, diagrams, and items of chemical plant arranged by the staff of the Chemical Research Laboratory.

In concluding, Prof. Morgan pleads for more organised research in inorganic and mineral chemistry and in the organic chemistry of vital products. Political and economic forces are bringing into prominence the urgency for a mutually advantageous interchange of commodities between the constituent nations and colonies of the British Empire, and in this pooling of natural resources these two branches of practical chemistry must play an essential part.

Geological History of the Bristol Channel.

In his presidential address to Section C (Geology) Prof. O. T. Jones deals with some episodes in the geological history of the Bristol Channel region. Among them the Triassic planation, the formation of the Mesozoic Cover, and the Miocene earth movements are regarded as the most important. During the Triassic period, intense erosion under arid continental conditions removed an enormous thickness of Palæozoic strata which had been folded by the Armorican movements commencing in late Carboniferous times. As a result, almost even-surfaced tracts of great extent were formed bordered by escarpments, among them one on each side of the Bristol Channel. There was then no indication of a tectonic basin in the region; rather it appeared that the channel area stood at a relatively high level, thus allowing the products of erosion to be largely removed to lower-lying areas of deposition. By analogy with the escarpments along the south side of the South Wales coalfield which have been proved to be of Triassic origin, it seems that the great plateau of Central Wales around the mountain masses such as Cader Idris and others that rise steeply above its surface may have been developed mainly by desert planation in the Trias. Afterwards the Channel region and neighbouring areas were invaded by the Mesozoic seas; the probable extent of the invasion of the Palæozoic areas of the west by the sea at various Jurassic periods is discussed in relation to the lateral variation of the Mesozoic formations.

During the Upper Cretaceous, it is fairly certain that the greater part, if not the whole, of the Palæozoic region had been covered by a considerable thickness of sediments.

The Miocene movements which are so largely responsible for the physical features of the south-east of England penetrated also into the south-west, both north and south of the Bristol Channel. The variation in the present level of the base of the Lias in the Vale of Glamorgan and in the Mendip region shows that the formation has been affected by considerable folding since its deposition; the type and scale of the folding are so similar to that of the Miocene movements in the south-east of England and northern France as to tend to the belief that the movements in the west were also in the main of Miocene age. Several axes of folding have been traced from the south-east of England into the Channel region. By these movements also the ancient plain of erosion traversing the Palæozoic areas of Wales and Devon was warped.

Comparison of the physical features in relation to axes of folding leads to the conclusion that those in the west are together almost a mirror image of those in the east. Thus the central plain of Devon is a continuation of the Hampshire basin; the high ridge of Exmoor represents an upfold of the ancient plain of erosion comparable with the anticline of the Weald, while the Bristol Channel is a syncline corresponding to the Thames Basin. North of the Channel the great plateau of Wales was warped in a south-westerly direction, thus leading to many important modifications in the drainage systems of that area.

The Species Problem.

In his presidential address to Section D (Zoology) Dr. W. T. Calman discusses "The Taxonomic Outlook in Zoology". Dealing first with the primary task of the systematist, the identification and description of the species of living animals, it is pointed out that one of the obstacles to obtaining a census of the animal kingdom lies in the fact that great sections of it are so imperfectly surveyed.

The intimate personal knowledge of the specialist, which in the days of Linnæus could embrace all the species then known, can now only cover a small portion of the field, and monographs, synopses or revisions which should be intelligible to the non-specialists are not available for many important groups. Attempts at a rewriting of the "Systema Naturae", like the British Museum Catalogues or the German "Das Tierreich", cover only a small part of the ground and are rapidly becoming obsolete. Meanwhile, the successively expanding volumes of the *Zoological Record* give a picture of systematic zoology being smothered under the products of its own activity. The confusion will grow steadily worse unless systematists come to

realise that the description of new species is a far less important thing than the putting in order of those that are already 'known', and until zoologists cease to regard taxonomy as a kind of menial drudgery to be performed by museum curators.

Even identification requires some kind of classification if it is only the classification of the dictionary. Since the time of John Ray, zoologists have believed in the existence of a natural system, and since Darwin it has been clear that this must be based in some way upon phylogeny. Dr. Bather, impressed by the prevalence of polyphyly and convergence, seems to think that phylogeny must be abandoned as a basis of classification, though it is not clear what he would substitute for it. Much current work and current speculation suffers from neglect of the taxonomic and phylogenetic outlook. Those departments of zoology most actively studied at the present day are preoccupied with the interplay of forces acting here and now and ignore the impressions that time may have left on the material of their study. It is as though a crystallographer studying a pseudomorph should endeavour to explain its form in terms of its chemical composition and the forces governing the arrangement of its molecules, without taking account of its history.

A few have even gone so far as to deny the existence of phylogeny. Prof. Przibram, in his theory of apogenesis, suggests that every species of metazoan has developed, independently of all the others, from a distinct species of protozoan. This is either one of the most significant results of recent biology or it is the *reductio ad absurdum* of much contemporary work. Although called a theory of evolution, it is, as regards the origin of species, no more than a doctrine of special creation at one remove. If we are to abandon belief in community of descent, the whole architecture of the "Systema Naturae" becomes meaningless.

It is significant that only on one point does Przibram speak with a hesitant voice, and that is where he mentions the geographical distribution of organisms. It is to be recalled that the opening words of the "Origin of Species" deal with geographical distribution. Przibram ends where Darwin began, and what for the one is merely the negligible residue of unexplained facts was for the other the very heart and core of the problem he set himself to consider.

Human Geography.

The subject of Prof. P. M. Roxby's address to Section E (Geography) is the scope and aims of human geography, a term now frequently employed in geographical literature, but liable to a more than ordinary degree of misconception.

The emergence and significance of human geography are discussed in relation to the modern conception of geography as a whole. The subject is of great antiquity, and the Greek view of it was in the main philosophical and scientific, but it suffered greatly from medieval formalism. It was Ritter and Humboldt who rescued what seemed to be a moribund subject and gave it individuality, coherence, and an immensely enhanced significance. This they did by claiming for it not a distinctive *segment* in the circle of knowledge—which is to destroy its very essence—but a distinctive method and objective in the handling of data common to other subjects. Ritter gave the keynote to the whole modern development of geography when he said: "It is to use the whole circle of sciences to illustrate its own individuality, not to exhibit their peculiarities. It must make them all give a portion, not the whole, and yet must keep itself single and clear." The same conception permeates the work of Vidal de la Blache, the founder of the French school of human geography, "Ce que la géographie, en échange du secours qu'elle reçoit des autres sciences peut apporter au trésor commun, c'est l'aptitude à ne pas morceler ce que la nature rassemble".

From the time of Ritter and Humboldt, workers in many fields of geography (geomorphology, climatic and biological geography, and human geography) have been guided by the same fundamental principles and methods, the central object being to exhibit the earth as a whole made up of related and interacting parts. Granted this unifying conception, the increasing capacity, on one hand, to formulate valuable and far-reaching generalisations as to the distribution and relationship of phenomena, and the imperative need, on the other, for a synthetic view of the earth, owing to the growing interdependence and inter-sensitiveness of its different regions, have inevitably increased the value and significance of geography in modern times.

Some of the principal contributions to the philosophy of human geography are next considered, and a comparison is made of the so-called 'Determinism' and 'Possibilism' of the schools of thought associated with the names of Ratzel and Vidal de la Blache respectively. The value is discussed in relation to such movements as that of regional planning of Febvre's dictum: "There are no necessities, but everywhere possibilities; and man, as master of the possibilities, is the judge of their use".

Human geography is then defined as the study of

(*a*) the adjustment of human groups to their physical environment, including the analysis of their regional experience, and of (*b*) inter-regional relations, as conditioned by the several adjustments and geographical orientation of the groups living within the respective regions. The adjustment has distinct but usually closely related aspects which form the main branches of human geography. These are discussed under the terms racial, economic, social, and political geography. It is permissible and desirable to pursue special studies of these various aspects, but they find their fullest fruition when they are brought together and inter-related in a full and comprehensive 'human ecology' of regions such as Cjivič has given us in his "La Péninsule balkanique: Géographie humaine". A plea is made for the study of historical geography as essentially human geography in its evolutionary aspects.

It is claimed that the point of view and type of outlook which human geography fosters were never more needed than in the present critical stage of mankind's development. Not only through its value as an educational instrument, but also through the programme of constructive work which it advocates, can it contribute to the realisation of the ideal of 'unity in diversity', and that seems the only possible ideal for the life of humanity on a planet which, however small applied science may make it, will always retain its infinite variety.

Rationalisation and Technological Unemployment.

Prof. T. E. Gregory's presidential address to Section F (Economic Science and Statistics), entitled "Rationalisation and Technological Unemployment", examines the bearing on unemployment of that reorganisation of industry which is now commonly known as rationalisation. The terms 'rationalisation' and 'technological unemployment' have obtained a widespread currency, and this has created an unfortunate impression that the world is now confronted by vast and mysterious economic problems of a kind hitherto unknown. The problems involved are indeed of the utmost importance, but when their character is analysed, it will be found that they derive their importance more from a change in scale than from the novelty of their nature.

The name of rationalisation has been given to a conscious process of industrial reorganisation which is taking place throughout the world, and of which the characteristic results are a growing control over markets, an increasing standardisation of processes and product, and a greater output per worker. These changes economise the amount of labour *directly* required per unit of output and effect, in so far as the distributive services are rationalised, a net reduction in the amount of labour required to place a unit of output in the hands of the final consumer. Given this trend, it may be asked does rationalisation inevitably cause unemployment as the result of the technological reorganisation involved?

Similar problems were discussed by the classical economists under the title of "The Influence of Machinery upon the Conditions of the Labouring Classes". They resolved the problem into its constituent parts, and these are still the fundamental issues to be faced. Does rationalisation involve unemployment (*a*) in a single industry, (*b*) in all industries taken together? Or is there some 'inherent' principle of human nature which will solve the problem, after transitional effects have been overcome? To-day we are again forced back upon general economic reasoning because the available statistics only suffice to establish a presumption that rationalisation has been responsible for part of the existing unemployment.

Since the rationalisation movement is international in character, and since it generally reduces cost per unit of output, no single country engaged in international trade can hope to contract out of its consequences. This in itself is sufficient reason for pushing ahead with rationalisation in Great Britain.

In the short run, rationalisation is not a remedy for unemployment, and on the contrary it may increase unemployment except to the extent that it stimulates demand in the constructional and equipment industries. In the long run, since rationalisation effects a lowering of real costs, there is no reason to suppose that the volume of unemployment will not again fall. It is impossible, however, to tell in what directions an increased demand for labour will manifest itself. Possibly in the future the occupied population will be less industrialised than in the immediate past. In this transition, whatever form it may take, a grave transfer problem is involved, and therefore the first and most obvious ameliorative measure must be an increase in the mobility of the working population.

Interdependence of Science and Engineering.

The presidential address to Section G (Engineering) by Sir Ernest Moir is entitled "The Interdependence of Science and Engineering, with some Examples". It begins with some interesting personal appreciations of some of the eminent engineers of the past, but in general is an attempt to indicate the interdependence of the engineer on the science of the physiologist, the bacteriologist, the economist and the all-important science of finance, all of which enable the engineer to carry out his destiny by entering new paths and opening up, by the aid of railways and roads, vast areas, to enable them to be made fruitful and suitable habitations for his fellows.

The three main sections of the address deal with (1) voids, (2) bacteriological and entomological sciences and their influence on civil engineering, and (3) economics of engineering construction. The influence of air- and water-filled voids is felt in such widely different instances as the combustion of fuels, the action of explosives, the drainage of subsoils, and the solidity of great marine structures subjected to the action of the sea. Special reference is made to the great breakwater at Valparaiso founded in 187 feet of water, upon a sand-

bank deposited by dredgers which has so consolidated itself that the fluke of an anchor let fall upon it does not penetrate its surface. Upon the sandbank have been placed layers of quarry rubbish and selected rock upon which rest 60-ton blocks. During a storm, a small movement of these blocks took place and this was attributed to the falling masses of water acting as hydraulic rams in the voids between the blocks. This is but one example which goes to show that the exact action of the sea on structures is waiting the solution of the scientific worker to determine what forces exist and are exerted by moving masses of water in great storms.

The execution of many great engineering works, such as the Panama Canal, has been possible only through the discoveries of Manson, Bruce, Ross, and others in connexion with the disease-carrying power of mosquitoes. During the construction of the Port of Para in Brazil, yellow fever was not entirely eliminated but there were few deaths. Research, however, is necessary on the Varugus disease, which causes trouble in the Varugus Valley through which the Central Railway of Peru runs; on bilharziasis, which is hindering the work on the dams and canals on the Blue and White Niles; and on blackwater fever, sleeping sickness, and the tsetse fly. Caisson disease, diver's palsy, or 'bends' has been largely prevented by the decompression method first used in the Hudson Tunnel, New York, in 1890–92; here the civil engineer has helped the science of medicine, thus making a return for some of the benefits received from the bacteriologist and medical man.

The third section of the address, on the economics of engineering construction, is a brief sketch of the various points which have to be considered by the contracting engineer, written with special reference to the carrying out of large civil engineering enterprises abroad and mostly undertaken for foreign governments.

Evolution in Material Culture.

In his presidential address to Section H (Anthropology), Dr. H. S. Harrison outlines and discusses a point of view, and an analytical method, in relation to the processes and steps through which the evolution of man's material culture has been effected, both subjective and objective aspects of various problems being considered. Stress is laid upon the predominant part played by opportunism in discovery and invention, and upon the extremely limited range of human foresight; aims and ends, as well as ways and means, are products of evolution, and only come into view as they are closely approached by an opportunist route. It is suggested that the "common faculties of the human mind", upon which so much weight is often carelessly laid, are so general in their nature, and so limited in their working by the conditions of the natural and artificial environment, as to be incapable of bringing about similarities in the products of discovery and invention, except in very simple cases. Man has always and everywhere an environmental mind, and environments differ so greatly that starting-points and opportunities are rarely the same, or even similar, except within the limits of common or intercommunicating cultures.

In the analysis of discovery and invention, a discovery may be regarded as a subjective event, which may or may not be applied objectively to material ends, and it is with applied discoveries alone that the technologist is concerned. These play a relatively smaller part in the evolution of artefacts or inventions, than in that of the methods and processes which constitute techniques, which may be called discovery-complexes. Artificially prepared substances, such as bark-cloth or bronze, may be termed discovery-products. All techniques owe their character to discoveries, few or many, usually of necessity following each other in a certain sequence, and parallelism in evolution ('independent invention') makes a big demand on coincidence, except where the sequence is short.

The term inventions, in its general vague sense, may be applied to all shaped or constructed artefacts, without prejudice to the need for a clear definition of the true inventive process and of the 'inventive step'. The 'small modifications' which have long been recognised as steps in the evolution of artefacts, are placed in two chief categories—those which may be called *variations*, no one of which produces an important change in the artefact in which it appears, though by summation the final result may be conspicuous; and those which represent definite and discontinuous steps in advance, and which may be called *mutations*. Variations may be casual, selective, or adaptive, and they do not necessarily influence functional efficiency; mutations, on the other hand, are always selective and adaptive, and their purpose is to increase efficiency. Two well-defined kinds of mutation can be identified; (1) those which owe their origin to discoveries made during the manufacture or use of the artefact involved (free-mutations), and (2) those which result from a prediction that an artefact may be improved by grafting on it a feature or a device which has developed in another context (cross-mutations). Since free-mutations arise out of discoveries, they are not inventions, and this term, in the strict sense of single inventive steps, may be confined to cross-mutations. From this point of view, true invention is a process of combination or hybridisation, in which foresight is necessarily involved.

The system of analysis proposed does not provide definite criteria for decisions on questions of independent evolution, but it enables a clearer conception to be formed of the evolutionary process, and of the probable discoveries, mutations, and variations, which have been traversed in sequence by material products of human ingenuity and industry. The general conclusion is strongly against the prevalence of independent evolution, on any significant scale, as a factor in human progress.

The Synthetic Activities of the Cell.

Prof. H. S. Raper's presidential address to Section I (Physiology) deals with the processes of synthesis in the animal cell. Up to the present

the catabolic activities of the cell have yielded more to the investigator than the anabolic. This is largely due to the fact that the former may be studied after death, whereas the latter are essentially those which occur only during life. Methods of experiment are thus very limited.

The great importance for physiology of elucidating the structure of organic substances produced by living organisms is emphasised and the debt due to organic chemistry for this is acknowledged. The usual synthetic methods of the organic chemist can, however, seldom have place in the living cell, owing to the severe limitations imposed by its extreme sensitiveness to environmental changes. The raw materials for synthesis are also very limited.

Our knowledge of the modes of synthesis of some of the more common components of animal organisms is dealt with. These include the bile acids, cholesterol, and the purine bases, where the raw material for synthesis cannot yet be said to have been ascertained. The possible synthesis of adrenaline from tyrosine and phenylalanine, to which it is closely related structurally, is discussed and the difficulties of the proof that such a process takes place in the cell are pointed out.

The synthesis of fat from carbohydrate, which was established by Lawes and Gilbert seventy years ago, is an instance in which the raw material for the synthesis is known with certainty but the chemical transformations involved are as yet obscure. A brief summary is given of the types of reaction which may well account for this synthetic process and the possibility of their occurrence in the cell is discussed.

The synthesis of glycogen is next dealt with. The evidence for and against its production by enzyme action is considered and it is concluded that the available information makes it probable that more than a mere reversal of enzyme action is concerned. This synthesis has so far never been obtained except in the living cell, and it seems probable that the substances from which glycogen is produced must at some stage form an integral part of the living protoplasm.

The raw material for protein synthesis, like that of glycogen, is known, but the mechanism by which the amino acids are joined together to form the very varied proteins which are produced by animal cells can only be guessed at. Here, again, the reversal of action of proteolytic enzymes has been invoked to account for the synthesis; but even if this did occur, it leaves the major difficulties unexplained. Protein synthesis, like that of glycogen, only occurs in the living cell, and the problem of its mechanism will probably only be solved when we know how protoplasm itself is produced. It is possible that cyclic changes in the cell may account for the production, time after time, of a protein of unvarying pattern. The change of an enzyme or its 'carrier' in cyclic fashion might produce changes of configuration which would lead to particular syntheses occurring optimally at various phases of the cycle.

The question of the site of protein and other syntheses in the cell is not without interest; it is possible that the nucleus of the cell is the main seat of synthetic activity. Many of the problems concerned in synthesis in the cell are problems of organisation, and for their solution a much more satisfactory objective picture of cell structure than we possess at present is essential.

Foundations of Child Psychology.

In his presidential address to Section J (Psychology) Prof. C. W. Valentine discusses the foundations of child psychology and their bearing on some problems of general psychology. He opens by enumerating the values of the study of the early years as: (1) the fascinating interest for those who love children or who marvel at the wonder of the developing mind, (2) to throw light on what is innate in the human being, (3) to counteract the tendency to interpret later childhood on the lines of adult experience, and to act as a check on the tendency to rationalise adult behaviour.

In recent times three schools of thought have devoted special attention to the study of early life. Psycho-analysts maintain that the first four or five years are the most important in the fixing of character. The behaviouristic school asserts that there are few genuine innate tendencies in man, and holds that any infant, if taken in hand early enough, can be 'conditioned' into almost any type of character. Lastly, the pioneer work of Dr. Arnold Gesell has provided tests suitable for infants of a few months old, and he claims that the results of such testing afford some evidence of correlations with normal mental development. Such tests, however, are themselves in need of testing, since little work has been done with young children and the present testers of young children are in the position of the testers of older children about twenty-five years ago.

Some criticisms that can be made are: (1) that the child of twelve months may be able to do some of Gesell's tests for the two-year-olds and yet fail in some of those for his own age; (2) that the tests are too dependent on the passing mood of the child; (3) that although Gesell maintains that fatigue and illness do not completely mask the stage of development, yet this would seem to be true only of the well established reflexes and not of the *nascent* functions.

As a result of a careful study of thought in little children, one is left with a strong impression that elementary thought processes appear very early. Evidence is brought forward that the spatial relation, causal relation, relation of likeness, and relation of evidence are apprehended at about three years of age. This is in direct opposition to the view of Piaget, who would not place such processes before the age of seven. It is necessary to guard against the assumptions that thought only develops when the corresponding word is used and that one word used by a child must necessarily have the same content of mean-

ing as when used by an adult. These thought processes, though, only appear at first sporadically, hence the necessity for careful daily observation in the child's own environment.

The outlook for the future is hopeful, and we may look forward to being able to test at about six months old a child's intelligence, its capacity for linguistic development, and its probable characteristic temperament. It must be admitted, however, that the field of infant psychology is still largely unexplored and that the method and technique are greatly in need of improvement.

Problems in Taxonomic and Economic Botany.

Dr. A. W. Hill's presidential address to Section K (Botany) is entitled " Present-day Problems in Taxonomic and Economic Botany ". In his opening remarks he refers to the work of J. S. Henslow, Thiselton-Dyer, and Harold Wager, and compares their services as teachers of botany. He then discusses some of the present-day problems in systematic botany connected with the ' species concept ' and the work of our great herbaria. Reference is made to the prevalence of hybridisation in New Zealand and to the work of Dr. Cockayne and of Dr. Lotsy and to the important effects on taxonomic work which must result from the fuller recognition of natural hybrids.

The question of physiological varieties is also referred to, and examples are brought forward from South Africa, in connexion with physiological varieties of *Pentzia* and *Salsola*, and of *Eucalyptus* in Australia, and other plants. The need of careful experimental work in connexion with taxonomy is emphasised, and a general review of the experiments that have been made in cultivating plants at different altitudes and under different soil conditions is given. Particular attention is paid to the work of Turesson in Sweden, and to the work which is being carried out in England, in co-operation with the British Ecological Society, at Potterne, in Wiltshire. These experiments are showing that, with individuals of known genetic origin, some remarkable changes can be produced when certain plants, particularly *Plantago major* and *Silene maritima*, are grown on different types of soil. The soils used in the Potterne experiments are clay, sand, calcareous clay, and calcareous sand. The importance of keeping accurate records in herbaria of the plants used in connexion with genetical and hybridisation work is referred to, and an account of the arrangements that are being made at Kew in these directions is given.

With regard to economic botany, some particulars are given of the interesting observations which have been made of the flower behaviour of Avocado pears in America, and also with regard to the fertilisation of the date palm, and the economic importance of physiological varieties is pointed out in such economic plants as para rubber, camphor, and *Eucalyptus dives*, the essential oil of which is used for the manufacture of thymol and menthol. Attention is also directed to the tung oil trees (*Aleurites*) which are now being introduced to our Dominions and Colonies, since it seems likely that they also may show various physiological types.

The importance of combining herbarium work with studies in the field is emphasised, and an account is given of the new activities in this direction which are being carried out at Kew, thanks to the grant made for this purpose by the Empire Marketing Board.

In conclusion, attention is directed to the need of more and better-trained workers in the fields of taxonomic and economic botany. The question of recruitment is discussed in the hope that it may be possible to widen the interest in biological science among those who are now being trained in the schools and universities of Great Britain.

A Policy of Higher Education.

Lord Eustace Percy's presidential address to Section L (Educational Science) is a plea for an appreciation of realities. What, in the rapidly changing conditions of contemporary life, are the changes actually required to enable our schools to meet the higher educational needs of the individual boy and girl ?—needs which are largely determined by the character of the services society will demand of them when they leave school. There is a tendency to-day to assume that full-time schooling up to sixteen years of age must be good for everyone, and that all we require is a sufficient variety of schools and curricula. The assumption ignores the fact that higher education worthy of the name is the very antithesis of the ' forcible feeding ' largely and necessarily prevalent in the elementary stage.

Higher education cannot work by compulsion, and the attempt to force pupils through this stage is foredoomed to failure. We are in face of an imminent danger of the methods of elementary education being pushed up into the higher sphere, wherein should be paramount the influence of " those standards of academic freedom and intellectual authority which it is the peculiar function of the universities to maintain ". Now, the university and technical college are in a special sense the mediators between the schools and society's demand for their product. The key to a new policy in higher education is the popularisation of the idea, already familiar to university appointments boards, that industry is the chief, and indeed the only direct, agent of social welfare. In supplying to it men trained for its practical requirements, the universities and colleges will be merely fulfilling their traditional function of synthesising research into doctrine and keeping new learning up-to-date with new knowledge. Their courses of training should be designed to react upon industrial practice, and their designers should aspire to acceptance by industry not merely as subservient trainers but as intelligent advisers. It is by such acceptance that American industry has been helped in some directions to eclipse that in Great Britain.

How are we to interpret industry's demand as conditioning practical measures of school reform? It is a demand for mental keenness rather than for physical skill, and though there are signs of a revival of the craft element in, for example, the furniture industry, it is broadly true that the demand for manual labour, skilled or unskilled, is giving place to a demand for labour involving at least some measure of abstract thinking and planning. This points to longer schooling. It would be a mistake, however, while we are still in this transitional stage, to risk starting the full-time schools of the future on wrong lines by forcing them to assimilate a mass of pupils who would stay on at school with no clear object. Our first aim should be to develop part-time education in technical schools and continuation classes for all children over fourteen.

The Hadow Report ideal of four-year courses of full-time schooling for all from eleven to fifteen years of age should be expanded into the wider ideal of five-year courses from eleven to sixteen, the first three in full-time schools and the last two either in full-time or part-time according to the pupil's needs. The full-time school should at every stage work in with the technical school so that the five-year course may be made a really continuous one. Above this stage there will be our traditional type of secondary school and our senior technical courses, bringing the pupil up to the college stage of higher education whether in the technical college or the university.

Veterinary Science and Agriculture.

Dr. P. J. du Toit, the director of Veterinary Services and Animal Industry for the Union of South Africa, in his presidential address to Section M (Agriculture), gives a general outline of some of the most notable achievements of veterinary science in recent years, and indicates the close relationship between this science, agriculture, and other sciences.

In the group of diseases caused by trypanosomes considerable progress has been made both in the treatment of infected animals by means of drugs, and in the campaign against the transmitter, the tsetse fly. Nevertheless, Dr. du Toit urges that the work be supported more liberally, since these diseases are holding up the advancement and civilisation of Africa.

Similar progress can be recorded in the elucidation of and the fight against the diseases caused by piroplasms. Drug treatment of some of these diseases is eminently successful. In others, for example, anaplasmosis, satisfactory methods of immunisation have been found. In yet others, reliance has to be placed on the control of the transmitting agent, the tick. The discovery of the rôle played by the tick in the transmission of these diseases is one of the landmarks in the history of biological science.

Amongst the diseases caused by ultra-visible viruses, rinderpest is a good example of a disease which has been eradicated from most countries by the application of modern methods. Great advances have also been made in the study of foot-and-mouth disease, rabies, and many other members of this group. Similarly, recent advances made in the science of bacteriology have rendered possible the control of various bacterial diseases, such as glanders and pleuro-pneumonia. Considerable interest is now centred on the problem of tuberculosis; work recently carried out in many countries with the so-called B.C.G. vaccine of Calmette and Guerin seems to indicate that a new weapon against this disease has been found.

Dr. du Toit further refers to the great importance of internal parasites (worms) to the livestock industry. Very good results have been obtained in the case of some of these infections (for example, stomach worms of sheep, *Hæmonchus contortus*) by means of drugs. Emphasis is laid on the fact that all available scientific knowledge must be applied to the control of parasitic worms, or else the sheep farming industry will be ruined. Great progress has also been made in the eradication and control of diseases caused by external parasites and poisonous plants. The problem of deficiencies, especially mineral deficiency in animals, is briefly referred to and it is shown how the cattle breeding industry has benefited from the application of the results of recent research work on this problem.

In conclusion, Dr. du Toit mentions the importance of nutrition and breeding for the livestock industry, and indicates how these problems are inter-related with the problems of animal disease. He pleads for further research on all these problems, and shows how South Africa has profited from the results of work carried out at the Veterinary Research Laboratory, Onderstepoort, Pretoria.

Printed in Great Britain by R. & R. Clark, Limited, *Edinburgh.*

Bristol more than Lord Justice Sir Edward Fry, F.R.S., the great international lawyer, who was born in Union Street, Bristol, and was a local naturalist of national reputation; John Samuel Budgett was a well-known local naturalist; while the third meeting in Bristol of the British Association, which took place in 1898, will always be remembered for the remarkable presidential address of Sir William Crookes, in which he directed attention to the limitations to the world's wheat supply and forecast the production of nitrogenous fertilisers from the air.

Recent Hydro-Electric Developments in the Alps and the Apennines.

By Dr. BRYSSON CUNNINGHAM.

THE widely extended and systematic exploitation within recent years of the valuable water power resources of Switzerland and Italy, hitherto lying latent among the mountain chains of the Alps and the Apennines, is one of the most striking features in connexion with the modern industrial and commercial developments of the countries in question, and it has been, and is being, attended by economic repercussions affecting various nationalities, including our own. Coal, the usual source of energy for power purposes where it can be mined, is lacking as a natural deposit, and, in the past, manufacturers using mineral fuel have had to rely in the main on importations from abroad, a very considerable portion of which came from Great Britain (South Wales and the Tyne district). The acute experience during the War, when these external supplies were cut off, brought home to the Swiss and Italian peoples the necessity of finding some internal means of making good a deficiency which tended to hamper, and even to paralyse, their industrial activities and placed them at the mercy of foreign interests. Not surprisingly, their attention was directed to the great potential value of the streams and lakes in the mountainous districts, where an untold quantity of water lay ready for utilisation and was capable, in a very large measure, of meeting commercial and industrial needs. These elevated reservoirs and mountain streams could be harnessed so as to produce electric current, which, in turn, could be distributed far and wide to suitable points of application.

The visitor to northern Italy and Switzerland at the present time cannot fail to notice the growing network of transmission lines which is spreading over the face of the country, scaling mountain flanks and ridges, traversing hills, valleys, and plains, and linking up cities and centres of population with an enormous spider's-web of copper and aluminium wire. Where, in past days, the landscape's most conspicuous artificial features were picturesque campaniles and church steeples, there are now to be seen, in challenging competition, lofty steel-framed pylons and standards, ranged in long files which, like the telegraph poles alongside a railway track, attend the traveller throughout his journeys.

The utilisation of water power for the generation of electricity, or rather its systematic exploitation for the purpose on a large scale, is a comparatively recent enterprise. Until the close of last century electricity was generated almost entirely by steam power. Canada—a country similarly handicapped to Italy and Switzerland in regard to its lack of natural coal deposits—which has now no less than six million water horse power harnessed to its electric generating stations, possessed in 1900 less than 250,000 realised horse power. In Italy, pioneer steps were first undertaken towards the end of the 'eighties, when in 1888 the city of Trento installed a plant of 500 kw., and between 1892 and 1895, when at Tivoli and Paderno scarcely less modest installations were inaugurated, the former to supply current to Rome at 5000 volts and the latter to Milan at 13,000 volts. It may be affirmed that these small undertakings marked the initiation in Europe of the great movement in hydro-electric exploitation which is so actively in progress at the present time throughout the world and has revolutionised in no small measure the methods and operations of manufacture and industry.

In this and two succeeding articles it is proposed to give a brief description of the conditions and present position in regard to hydro-electric developments in Switzerland and Italy, and to set down certain personal impressions formed during a recent series of visits to some of the leading and most modern installations.

Both countries have mountain systems of great magnitude and extent. The towering heights attained by the ranges have naturally a very marked influence in conferring a notable degree of head, or pressure, on supplies of water which can be collected, diverted, and utilised for power purposes. In this respect, however, it is desirable to point out a distinction between the two classes of mountain ranges. The essential characteristic of the Alps is their abundance of glaciers, with extensive areas of frozen snow and ice, which cover their summits and topmost slopes practically in perpetuity. From the gradual and periodical melting of these masses of ice and snow come the streams and waterfalls which constitute so charming a feature of the landscape. But the flow is intermittent and limited to those seasons of the year in which the temperature is sufficiently high to cause thawing. In other words, it is only during the summer months that supplies of flowing water from these sources are available. During the rest of the year they are imprisoned in a solid state.

Fig. 1 shows a view of the Piz Palü and the Palü Glacier in the Bernina Range, one of the sources of supply of the Brusio Power Works in the Canton of the Grisons, Switzerland.

In the Apennines, on the other hand, there is an absence of glaciers and very rarely do these heights

FIG. 1.—Piz Palü and Palü Glacier, Bernina Range, Canton of the Grisons, Switzerland. By courtesy of the Brusio Kraftwerke, Poschiavo.

reach the level of perpetual snow. The consequence is that, as regards water supplies, an entirely different regimen prevails. It is not from glaciers and snowfields that the watercourses of the defiles and valleys are fed, but from the ordinary rainfall, which is seasonal and chiefly in evidence during the autumn and winter, whereas the summer precipitation is slight.

The difference may be summed up by saying that the hydro-electric installations among the Alps are, in general, actuated by lofty heads and small (even, in some cases, exiguous) supplies, with a service which is only fully effective during the summer, whereas those among the Apennines have a more moderate fall with better and more copious supplies, frequently in association with impounding reservoirs in the lower levels, the seasonal activity being most pronounced during the autumn and winter.

Impounding reservoirs, however, are not limited to the Apennine regions: they are also a feature of certain Alpine installations, though in that case they are located at considerably increased heights, and their area is naturally more circumscribed. Moreover, they have been formed under greater constructional difficulties than those on the lower slopes, which, although in some cases requiring dams of greater length, are more readily and easily accessible. The impediments in the way of the conveyance of material and the carrying on of works in the higher regions are obviously very great and the cost of such operations is correspondingly heavy.

In the formation of storage reservoirs, regard has naturally been had to the possibilities of utilising the configuration of the district to the best advantage. Despite the existence, however, among the mountain ranges of quite a number of natural lakes which form admirable reservoirs of water suitable for power purposes, the physical conditions have not always been favourable, and, the distribution being irregular, in many cases, use has had to be made of other sites which have required extensive constructional operations in order to develop them adequately as basins of supply. Some of these artificial basins, especially those of low or moderate altitude, are of remarkable size; there are about fifty or so in Italy alone, each containing more than one million cubic metres of water. Perhaps the most notable of recent years is the reservoir of Tirso, in Sardinia, which has a maximum capacity of about 400 million cubic metres.

One of the earliest examples is the reservoir at Cismon, in the province of Belluno, by means of which the Società Adriatica d'Elettricità has been able to impound four million cubic metres. It possesses some interesting features. Constructed between 1905 and 1908, and the first of its type in

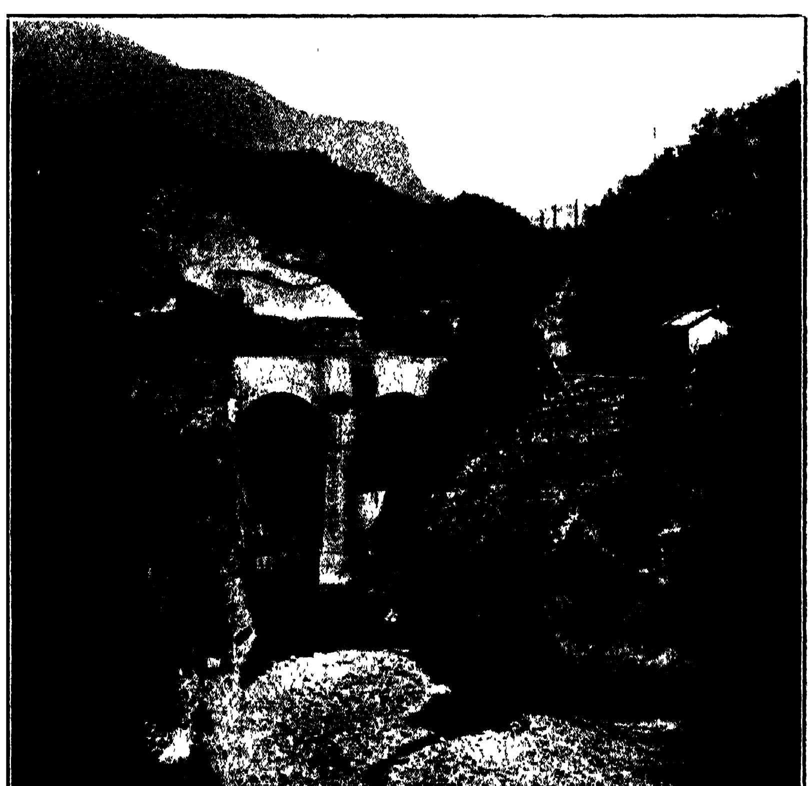

FIG. 2.—Cismon Dam. By courtesy of the Società per l' Utilizzazione delle Forze Idrauliche delle Veneto.

Italy, the masonry dam, which is shown in Fig. 2, is in the form of a slender arch supported by rock abutments on each side so closely adjacent that the chord of the arc is only 40 metres in length. The thickness of the dam at the top is 3 metres, increasing to 12 metres at the base. The height is 44 metres. The overflow, sometimes 2 metres in depth, passes over a rectilinear crest supported by the flanks of the dam and a central pier. The conduit to the power station (shown in Fig. 3) takes the form of a tunnel 1½ kilometres in length, at the end of which are two pressure tubes of 1·9 metre diameter. These, with a fall of 52 metres and a flow of 18 cubic metres per second, feed two generators, the joint capacity of which is just under 10,000 horse power.

Another point to which attention may be directed as characteristic of both Alpine and Apennine installations, arising out of the intermission of their supplies, is that for the purpose of securing constant supplies of power it has been necessary to supplement them in a number of cases by 'thermic' or steam generating stations, in which current is generated by power derived from the consumption of fuel. Thus it will be seen that, as distinct from purely hydro-electric power stations, such as those in eastern Canada, which are more or less in constant action under the energy derived from streams and rivers at low altitudes with plentiful supplies of water, the power stations of northern Italy are worked in conjunction with thermic stations which come into operation when the natural water power is suspended or is insufficient. These two sets of stations have to be connected and linked up in a compensatory system, which complicates matters a little more than would be the case if the energy were forthcoming from a single source. The six leading hydro-electric systems in the Italian peninsula, namely, the S.I.P. (Società Idroelettrica Piemonte), Edison, Adamello, Adriatica, Central and South Groups, have six thermic stations, at Turbigo, Genoa, Raconga, Marghera (Venice), Leghorn, and Naples respectively.

Attempts have been made from time to time to determine within reasonably close limits the total available supply of hydraulic energy in various countries. In all computations of this kind there is much scope for error, due to the unreliability and insufficiency of the data at hand. Conclusions, therefore, have necessarily been of the nature of mere approximations, subject to correction as further investigations have been made and the results of actual utilisations have become known. At the present time, estimates are still too vague to permit of any close or rigorous figures, but for the purposes of this notice it may be said that such statistics as are published lead to the conclusion that the available water horse power of Italy is of the order of five to six millions,[1] and that of Switzerland rather less—say four millions.[2] These figures must be taken with reserve; they are probably, almost certainly, under-estimates, but they may serve as the basis of an interesting comparison with similar estimates applicable to Canada, where, as noted in a recent article in NATURE,[3] the available horse power is calculated to exceed forty millions. On the other hand, the area of Canada is more than thirty times as great as Italy and 233 times as great as Switzerland. Accordingly it will be seen that, despite the magnitude and impressiveness of the developments which have been proceeding on the North American continent, the potential intensity of development on an area basis is much greater in the European countries.

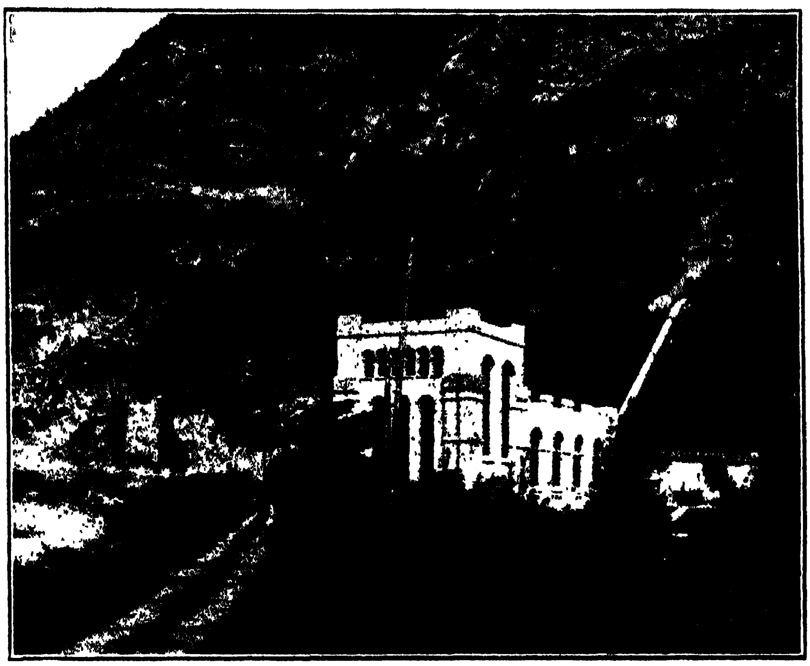

FIG. 3.—Cismon Power Station. By courtesy of the Società per l' Utilizzazione delle Forze Idrauliche del Veneto.

During 1929, some 400,000 additional water horse power was installed in new, or extended, hydro-electric stations in Italy, bringing the aggregate of installations up to about 4½ million horse power. The latest available figures for Switzerland indicate that some 2½ million horse power had been realised in various installations up to the end of 1929. It must be admitted, however, that the difficulties in the way of instituting an exact census of all installations, large and small, public and private, direct acting and transmissional, are such that the returns, while substantially correct, may not be quite precisely so. At a stage when progress is rapid and the situation changes from month to month, absolute accuracy is, perhaps, of no great account.

[1] *Vide*, Table IV., "Power Resources of the World"; published by London World Power Conference, 1929.

[2] This is the official estimate of the Swiss Service des Eaux as contained in the *Rapport du Conseil Fédéral sur sa Gestion en 1929*. A much higher figure is given in the London World Power Conference Report.

Obituary.

J. A. LE BEL, FOR.MEM.R.S.

THE death of Joseph Achille Le Bel, which occurred in Paris on Aug. 6, removes a veteran who had been closely associated with the rapid development of organic chemistry during the latter part of the last century. Le Bel was born at Pechelbronn, Alsace, on Jan. 21, 1847, and was a nephew of Boussingault, the agricultural chemist. He was a student at the École Polytechnique from 1865 to 1867 and became successively assistant to Balard, the discoverer of bromine, at the Collège de France, and to Würtz, at the École de Médecine, in Paris. For some time he was in charge of the petroleum workings at Pechelbronn, in which his uncle was interested; he became and remained an ardent partisan of Mendeléeff's view that the petroleum deposits result from the action of steam on metallic carbides at volcanic temperatures.

Le Bel holds an honoured position in the history of science as one of those eminent French natural philosophers who discovered and worked out the earlier consequences of optical rotatory power. Arago observed in 1811 that the plane of polarisation of a beam of polarised light is deflected by passage through a plate of quartz cut perpendicular to the optic axis; in 1815 Biot found that certain organic liquids, such as turpentine, are also optically active in the same sense. In the 'fifties and 'sixties, Pasteur concluded from his classical investigation of the tartaric acids that the optical rotatory power of aqueous solutions of these organic compounds arises from asymmetry of their molecular configurations. No progress was made, however, in the problem of ascertaining the definite arrangement in three-dimensional space of the atomic components of optically active molecules, called for by Pasteur's fundamental conclusion, until the doctrine of the asymmetric carbon atom was enunciated.

The theory of the asymmetric carbon atom was put forward independently and practically simultaneously by van 't Hoff and Le Bel in 1874; after a brief period of discussion, accompanied by a certain amount of lively ridicule, the theory became universally accepted and to-day forms the foundation of the vast subject of the stereochemistry of carbon compounds. The theory was evolved in a somewhat different fashion by its two authors. Van 't Hoff proceeded from the assumption that, in such a molecule as that of methane, CH_4, the four valency directions of the carbon atom are directed from a centre, representing the carbon atom, towards the apices of a regular circumscribing tetrahedron, the four hydrogen atoms being centred at those apices. In the substitution derivatives of methane of the types, CX_3Y, CX_2YZ, X, Y and Z being univalent radicles, no isomerism should exist if the four radicles lie at the apices of the tetrahedron as foreshadowed by the theory; when all four radicles attached to the central carbon are different, as in the type CWXYZ, two isomerides should exist, the space configuration of one being the mirror image of that of the other. A carbon atom so attached to four different radicles is termed asymmetric, and, in accordance with the conclusion of van 't Hoff and Le Bel, all substances which contain one asymmetric carbon atom in the molecule have been found to exist in two mirror image, or enantiomorphously related, configurations, of arithmetically equal but algebraically opposite rotatory powers.

Le Bel arrived at the theory in a somewhat different manner. He discussed the mode in which the four univalent radicles attached to a quadrivalent carbon should arrange themselves as a pure question of equilibrium, and hence arrived at the tetrahedral environment of the central carbon atom with the same consequences, as regards asymmetry, as those of van 't Hoff. It is not yet settled whether van 't Hoff's view, that the carbon atom carries four valency directions directed towards the four apices of a circumscribed regular tetrahedron, is preferable to that of Le Bel, but the tendency of modern organic chemistry is certainly towards the Le Bel implication that the four carbon valency directions are not so fixed. Probably, however, both men were making in 1874 an incomplete statement of the same thing; although more than half a century has elapsed, it is not yet possible to state the theory of the asymmetric carbon atom in more definite and explicit terms than was done at that date.

Le Bel was the first to separate an optically active component from the synthetic mixture of the two mirror image components of a compound containing an asymmetric carbon atom; he did this in most cases by taking advantage of the selective destructive action of lower organisms on the laevo- and dextro-isomerides. He was also the first to show that when the asymmetric carbon atom of an optically active substance of the type, CWXYZ, becomes symmetric by conversion into the allied compound, CX_2YZ, the optical activity disappears.

Later, Le Bel extended his stereochemical conceptions to quinquevalent nitrogen compounds and announced in 1891 that he had been able to obtain optically active methylethylpropylisobutylammonium salts; this observation could not be confirmed by others, and is no doubt mistaken. The laboratory technique for dealing with such complex substances had not then been sufficiently worked out, and it was not until 1899 that the first optically active substituted ammonium salts containing an asymmetric quinquevalent nitrogen atom, but no asymmetric carbon atom, were first prepared.

Le Bel did not publish a great amount of experimental work, probably because he held no academic post and so found few collaborators; his writings cover, however, a wide range of subjects and are permeated by a quite uncommon philosophic spirit. He was an individualist and mixed little with his scientific colleagues; he was intolerant of officialdom in any of its aspects, and was wont to express

his contempt of bureaucracy with some vigour. His originality of thought, his outspokenness, and his unconventionality, indeed bohemianism, made him somewhat difficult of access, but in congenial society he was a delightful companion, full of knowledge of the world and sparkling with anecdote and caustic wit. He maintained his interest in science to the end, and, so late as April last, offered a money prize for the rediscovery of a microscopic green alga, found and lost by him, which had the power of converting atmospheric nitrogen into ammonia.

Le Bel was president of the French Chemical Society in 1892; he was a Commander of the Legion of Honour and a member of the Paris Academy of Sciences. He was elected an honorary fellow of the Chemical Society in 1908 and a foreign member of the Royal Society in 1911; in 1893 both he and van 't Hoff became Davy medallists of the Royal Society.

W. J. POPE.

News and Views.

PROF. F. O. BOWER, whose presidential address to the British Association is printed in our Supplement this week, is an outstanding figure in British botany. Following a brief period as lecturer in botany at the Imperial College of Science, South Kensington, he became Regius professor of botany in Glasgow in 1885, and there during his forty years of tenure of his chair devoted himself with boundless energy to the study of problems of plant morphology and affinity. His influence as a teacher, investigator, and administrator has been marked, and it may truly be said that he has done more than any other living botanist to form botanical opinion and stimulate research in his field of special inquiry. As a writer he has shown rare gifts of both analysis and synthesis. He is the author of many publications which have been widely read and constantly admired, both for their clarity of expression and constructive reasoning. Chief among these are "The Origin of a Land Flora", published in 1908, and his works on the "Ferns", published since 1923; but he has also devoted himself to more popular exposition in such works as "The Botany of the Living Plant" and "Plants and Man". He has held the presidential chair of the Royal Society of Edinburgh, has thrice been president of the Botanical Section of the British Association, and among the numerous other distinctions which have fallen to him in recognition of his work are a Royal Medal of the Royal Society, the Linnean Medal of the Linnean Society, and the Neill Prize of the Royal Society of Edinburgh.

To one so deeply interested as Prof. Bower in both the details of morphological study and broad philosophical discussion, the choice of subject for his presidential address to the British Association at Bristol may have been easy, and in choosing as his theme "Size and Form in Plants" he has presented a topic which has for long claimed his attention. Starting with Darwin's view of life that from simple beginnings creatures of endless form and beauty have been, and are being, evolved, he touches lightly on a probable common origin of the kingdoms of plants and animals, their early divergence in descent, their increasing size and complexity, and the attainment of those varied forms of colonial life which we call the higher creatures. If the offspring fail to separate, colonial life is begun and the surfaces of interaction with the outer world are restricted; growth of the dual partners proceeds to its limits, and division, without separation of the offspring, follows. Thus step by step the stature of the colony increases, the problems of life change for the individual components, and reflect themselves in the variously differentiated tissues which they come to compose. But though many of the units may die without dividing, and thus contribute in varied ways to the services of the colony as conductive and supporting tissues, in plants there is a residue of cells, mainly massed at the growing points of stem and root, which up to the limits of size and form of the colony may continue to grow, divide, and contribute still further to the stature of the colonial being. On the other hand, it would appear that the extreme stature mechanically possible for a tree-trunk thus evolved is about 300 feet, and that this coincides approximately with the limits of height of the canopy of a tropical forest; that the members of the plant kingdom range in size between the microbe and the forest tree, and that the varied forms of colonial plants which have won success in descent have been determined in large measure by the size factor.

IT is to the elaboration of this thesis that Prof. Bower's presidential address is largely devoted, and in its development the surfaces through which the physiological exchanges within the plant, and with the outer world, are maintained, are discussed. In brief, it is held that both in extent and arrangement a plan of external form and internal differentiation may be satisfactory up to a limit of colonial stature, that if the plan is maintained beyond this limit the creature fails, that throughout descent failures from this cause are manifold, and that Nature has not failed to seek and find escape from extinction for many of her creatures, as their size increased, in re-arrangement of the surfaces of physiological exchange, both internal and external. It is on this view that Prof. Bower has sought once more to direct attention to the wonders of form and structure which pass coldly to-day under the science of morphology, and to place them as reasonable and varied solutions which have been found to the problems of life in its higher forms. The address closes with a note of appeal to all who may assist in rendering the link of usefulness between pure research and application stronger, and a high appreciation of all that has within recent years been attempted and accomplished in this direction.

IF one may judge from the first days of the annual meeting of the British Association now in progress at Bristol, the gathering will rank as one of the most

successful in recent years. The organisation of the meeting is very complete, the reception-room being set in the commodious and beautiful Great Hall of the University and the sections all adequately housed near it. The figures of the attendance to date exceed 2500, many visitors being attracted no doubt as much by the interest of the city and its environs as by the scientific papers. As we go to press, Prof. Bower's presidential address is being delivered in the Colston Hall, which visitors to the previous meeting in 1898 may remember was dramatically burnt down two days before that meeting. The first of the citizens' lectures is being given on Sept. 4 by Sir Daniel Hall, on "Apples: the Effect of Research on Production". This subject has special local interest in view of the work of the University Agricultural Station, which was founded from the earlier Fruit and Cider Institute at Long Ashton. On the same evening the Lord Mayor is holding a reception in the Museum and Art Gallery, followed by a dance in the Victoria Rooms. Amongst other items of special interest in the programme for Thursday are the address by Prof. Abercrombie to the conference of delegates, on national parks, and also the inspection of the Henry Herbert Wills Physical Laboratory, with demonstrations to members of Section A. Visits to Messrs. Wills' tobacco factory and short tours of historic Bristol, which are taking place daily, are being well patronised. The handbook for the meeting is in magazine form, and includes articles on previous meetings of the Association at Bristol and on the development of the University, together with an illustrated account of the old and new city of Bristol.

BY the retirement on Sept. 1 of Mr. H. W. Dickinson, the senior keeper, the Science Museum, South Kensington, loses one of its best-known officers. Born at Ulverston, Lancashire, sixty years ago, Mr. Dickinson was educated at Manchester Grammar School and Owens College, and after gaining practical engineering experience in various works, in 1895 he joined the staff of the Science Museum, when it was still part of the South Kensington Museums. During his thirty-five years' service he has served under four directors, General G. R. Festing, Mr. W. I. Last, Sir Francis Ogilvie, and the present director, Sir Henry Lyons, and has been associated with all the modern developments of the Museum. As an assistant keeper and a keeper he has been responsible for the compilation of various catalogues; while as senior keeper of the engineering collections, the task fell to him of installing the important exhibits in the ground floor of the new galleries opened by the King in 1928. In addition to his ordinary duties, he has acted for sixteen years as secretary to the Advisory Council of the Science Museum, presided over by Sir Hugh Bell, and during the War was secretary to a panel of men of science set up by the Ministry of Munitions for the examination of inventions.

MR. DICKINSON'S travels have made him widely known in the United States and on the Continent. Since the formation in 1920 of the Newcomen Society, he has acted as honorary secretary, and recently he has accepted the honorary secretaryship of the Second International Congress of the History of Science and Technology, which will meet in London next June and July under the presidency of Dr. Charles Singer. He is the author of a life of Robert Fulton, and the joint author, with Mr. Rhys Jenkins, of the fine memorial volume on James Watt issued in 1919 in connexion with the Watt centenary celebrations. Though his retirement marks the end of Mr. Dickinson's official career, we are glad to know that it will not mark the cessation of his activities in furthering the study of engineering and technological history.

THE Canadian Supplement of the *British Medical Journal* of Aug. 30 contains the full text of Lord Moynihan's Lister oration delivered on the occasion of the annual meeting of the British Medical Association at Winnipeg on Aug. 29. Lord Moynihan described Lister as the greatest material benefactor the world has ever known, and as one who has saved more lives than all the wars of all the ages have thrown away. Lister created a new world for surgery by making it possible to prevent infection in new wounds and to deal more successfully than before with wound infection already established. This achievement was due to the recognition of a new principle, namely, that surgical infection was due to living microbes with their power of infinitely rapid propagation in wounds. In other words, Lister's success was due to the application to surgery of Pasteur's researches on putrefaction and fermentation, to which his attention was first directed in 1865 by Thomas Anderson, professor of chemistry at Glasgow. At first, as the result of Pasteur's influence, Lister regarded the air as the chief source of danger, and therefore made considerable use of the carbolic spray, which he afterwards discarded; but he afterwards convinced himself that the surgeon's fingers and instruments were more to be feared than the air. In spite of the scepticism, ridicule, and indifference of many eminent contemporary surgeons, Lister succeeded in reducing almost to zero the incidence of erysipelas, pyæmia, hospital gangrene, and tetanus, which had hitherto been rife in the Glasgow Infirmary as in other large hospitals, and in undertaking successfully operations which had hitherto been regarded as too dangerous. In conclusion, Lord Moynihan attributes Lister's ultimate triumph not so much to his supreme intellectual gifts as to his idealism, enthusiasm, earnestness, and courage.

DR. ALEŠ HRDLIČKA has recently returned to Washington from Alaska, where he has spent the spring and early summer in investigating the ethnology of the Eskimo of Kuskokwim River. According to a report circulated by Science Service of Washington, D.C., Dr. Hrdlička found that the Eskimo in this area now number about three thousand. They had not previously been studied on the spot, and he was fortunate enough to be able to measure a considerable number of them. He also unearthed a number of very ancient burials, and by measuring the skeletal remains was able to establish their physical characters over a considerable period, possibly some hundreds of years. The results show that the type has remained constant

for a long period of time, and Dr. Hrdlička concludes, it is stated, that it represents the old original type of Eskimo from which other types have developed. The distinctive feature in this type is that it lacks the extraordinary facial development and outstanding jaws characteristic of the Eskimo of Greenland and other Arctic regions. The differentiation is so marked, especially in the older specimens, as to warrant, in Dr. Hrdlička's view, the conclusion that the original type was Indian and to set definitely at rest any question that the Eskimo are of a different and distinct race. No doubt more will be heard of this matter at the International Congress of Americanists which meets at Hamburg on Sept. 7–13.

AN article by the special correspondent of the *Times* in the issue of Aug. 30 gives an account of some of the results obtained by Prof. Siegfried Loeschke on a site in Roman Trier on the Moselle. The site in question, which lies outside the original walls of the city founded by Augustus in the Altbachtal, was discovered by Prof. Loeschke in 1924. The excavations were begun in the following year and continued until Aug. 9 last, when they were closed down owing to economic difficulties. They have produced some remarkable results, especially in their bearing upon the religious beliefs and culture of the pagan Treveri, of whom little was known previously. In fact, these excavations have been pronounced by German authorities to be the most important for many years in the sphere of Romano-German cultural development and in the additions they have made to knowledge of theistic cults on Celtic soil. No less than twenty-four temples and twenty-nine chapels have been discovered in the course of these excavations. Among the more interesting finds during the current season is a life-sized marble statue of the goddess Arduinna, from whom the Ardennes takes its name; this statue is pronounced to be the finest marble found at Trier since 1845. Another is a representation in baked clay of the Celtic goddess of the woods and waters, Artio, in the form of a bull with forelegs arched over the figure of a youth. This is headless, but otherwise complete with pediment. A number of representations of other deities have been discovered, some of which are still unidentified; but in 1928 among a hundred clay statuettes found in a building adjoining a temple were a number unquestionably intended to represent the Germanic deities, Wodan, Ziu, and Donar, which were equated with the Roman deities, Jupiter, Mars, and Hercules. This find confirms, in Prof. Loeschke's view, the statement of Roman writers that the Germanic tribes worshipped Hercules, though the Gauls left no such tradition.

FROM the publication of some of the particulars of the will of the late Miss Sarah Priestley Wainwright, a great-granddaughter of the eminent natural philosopher Joseph Priestley, we learn that the diploma and seal in box sent to him by the Empress Catherine of Russia, together with his Copley Medal, have been bequeathed to the Royal Society. This medal was awarded to him in 1773 for his "Experiments on different kinds of Air", read to the Society two years before he announced the discovery of oxygen. But from an interesting letter from Franklin to Canton, reprinted in Weld's "History of the Royal Society", 1848, it will be seen that it had been proposed to award him the medal in 1767 for his experiments in electricity. When making the presentation in 1773, Sir John Pringle, the president, said to Priestley: "In the name and by the authority of the Royal Society of London, instituted for the improvement of Natural Knowledge, I present you with this medal, the palm and laurel of this community, as a faithful and unfading testimony of their regard, and of the just sense they have of your merit, and of the persevering industry with which you have promoted the views, and thereby the honour of the Society. And in their behalf, I must earnestly request you to continue those liberal and valuable inquiries, whether by prosecuting this subject, probably not yet exhausted, or by investigating the nature of other subtill fluids of the universe." Shortly after being awarded the medal, Priestley was elected one of the eight foreign associates of the Paris Academy of Sciences.

As broadcast receiving sets with outside aerials are much used in Great Britain, the following account of what happened when the aerial of a house in Doncaster was struck by lightning will be of interest. It is probable that some one had forgotten to earth the aerial after using the set. A report of the damage done (with a diagram) is given in the *Electrical Times* for Aug. 28. The house was on high ground, somewhat exposed, and was near the middle of a long row of houses. The horizontal aerial wire was attached to the top of a 38-foot pole through an insulator and to a short pole on a chimney-stack on the roof. It then went downwards to two iron brackets and insulators which kept it away from the building. Finally it entered a room on the ground floor through a leading-in tube and was attached to the receiving set. The lightning flash seems to have struck the horizontal part of the aerial and branched in each direction. The insulator at the pole end was smashed and the aerial fell. In the other direction, the lightning seems to have sideflashed down the outside of the chimney-stack, as the lead on the roof was pulled up some six inches round the base of the stack. The insulator on the top bracket was smashed, a charge sideflashing through it into a wall of lath and plaster separating two rooms, apparently bursting the wall and scattering plaster into each room. The insulator of the lower bracket was unbroken, a charge arcing to the bricks and scattering portions of them a distance of about thirty feet. The rest of the charge entered the receiving set and burst a condenser in it. On raising the lid, it looked as if everything had been sprayed over with pitch, doubtless from the condenser; but no damage was done to the valves or the transformers. The house fuses for the electric-lighting mains were blown and three electric lamps had their filaments broken, but the insulation of the mains was undamaged. Most sets with outside aerials have lightning protectors. It is advisable, therefore, to see that they are switched on during a thunderstorm.

"THE present centrifugal movement towards specialisation with its resultant divergency of interests and tendency to misunderstanding between workers" was deplored by Mr. C. E. Andrews, Government Geologist in New South Wales, in his recent presidential address to the Australian and New Zealand Association for the Advancement of Science. He commended the suggestion once made by Gilbert, the philosopher-geologist of America, who advocated "the extensive use of the 'Intellectual Excursion' amongst workers", meaning thereby that they should take an intelligent interest in work going on in other fields besides their own. Such excursions may prove a fruitful source of inspiration, an instance of which was given by Mr. Andrews in Darwin's utilisation in the "Origin of Species" of Mathew's work on "Naval Timber". He might also have added that perhaps Darwin's masterpiece would never have been written had not the author perused Malthus's "Essay on Population". But altogether apart from the stimulating effect of occasional excursions into other fields, there is the enlargement of the mind which accompanies the 'synoptic' point of view. Men of science have sometimes been charged with Philistinism, and specialism may easily tend in this direction. The best antidote would be that every student should work out some sort of a philosophical outlook for himself; but this he will scarcely do if he is blind to the importance of every subject except his own.

THE University of London Animal Welfare Society has sent us a letter appealing for information about the condition under which badgers and otters exist to-day in Britain. These are elusive animals and their secretive and nocturnal habits must make the collecting of accurate information about their distribution and numbers wellnigh impossible, but a present-day census, even if incomplete, would give a kind of standard by which fluctuations in future years might be tested. Helpers in this good work are requested to answer a series of questions with the view of elucidating: (a) The localities now inhabited by badgers and otters, their numbers and the years of special abundance or scarcity, the nature of their habitats, and natural causes of death; (b) their habits, especially in regard to their economic relations to the farm, game-preserving, and fishing; (c) methods of trapping and their desirability or otherwise from the point of view of cruelty involved, the nature of the 'sport' the creatures are subject to, and whether it is desirable as an effective means of destruction. Replies to the queries, which have been stated above in summary, should be sent to Miss Ada Hallett, 34 Acre Lane, London, S.W.2.

DR. JOHN WALTON, lecturer in botany in the University of Manchester, who has been appointed to the Regius professorship of botany in the University of Glasgow (NATURE, Aug. 30, p. 332), is well known as a distinguished authority upon fossil plants, particularly those of the Carboniferous system, and his appointment to the University of Glasgow seems particularly appropriate in view of the fact that the department of botany in that University houses the great Kidston collection of fossil plants with its accompanying library. The new professor may be expected to carry on the morphological traditions of the Glasgow school associated particularly with the name of Prof. F. O. Bower.

DR. J. A. CARROLL, assistant director of the Solar Physics Observatory, Cambridge, has been appointed professor of natural philosophy in the University of Aberdeen in succession to Prof. G. P. Thomson. Dr. Leslie J. Comrie, deputy superintendent since 1925 of the Nautical Almanac Office, has been appointed superintendent of the office in succession to Dr. P. H. Cowell, who has retired under the age limit after twenty years' service.

WE have received vol. 12 (1929) of Experimental Researches and Reports published by the Department of Glass Technology, University of Sheffield. This contains reprints of a number of papers published from the department in different journals covering various sides of the industry.

THE U.S. Coast and Geodetic Survey publication entitled "Directions for Magnetic Measurements", by Daniel L. Hazard, was reprinted in 1921, and a further (third) edition (serial number 166, price 30 cents) has now been issued. It gives the theory of magnetic instruments, and directions for their use on land and at sea. The principal instruments considered are the ordinary magnetometer, the dip circle, and the dip inductor; in further editions some account of electrical means of measuring the magnetic force may be hoped for. Brief instructions as to the operation of a magnetic observatory are included, but a separate detailed manual on that subject is in preparation. There is also a brief chapter on earthquakes and seismographs. The manual is a very valuable and inexpensive short treatise on practical magnetic work.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant road engineer in the Roads Department of Southern Rhodesia—The High Commissioner for Southern Rhodesia, Crown House, Aldwych, W.C.2 (Sept. 7). An instructor in veterinary science under the Glamorgan Agricultural Committee—The Director of Agriculture, 17 Park Place, Cardiff (Sept. 8). A veterinary surgeon under the Municipal Commissioners of George Town, Penang—Peirce and Williams, 1 Victoria Street, S.W.1 (Sept. 9). A half-time assistant in the Geology Department of the University College of Swansea—The Registrar, University College, Singleton Park, Swansea (Sept. 12). A demonstrator in chemical pathology in the University of Manchester—The Registrar, University, Manchester (Sept. 13). A junior lecturer and demonstrator in the chemical department of East London College—The Registrar, East London College, Mile End Road, E.1 (Sept. 13). A research officer for investigations of fisheries, Andaman Islands—The Secretary to the High Commissioner for India, General Department, India House, Aldwych, W.C.2 (Sept. 17). A senior factory inspector under the Ministry of Labour of the Government of Northern Ireland—The Secretary, Civil Service Commission, 15 Donegall Square West, Belfast (Sept.

20). An assistant lecturer in chemistry in the University of Birmingham—The Secretary, University, Edmund Street, Birmingham (Sept. 20). An assistant part-time lecturer in the biology department of the Plymouth and Devonport Technical College—The Secretary for Education, Education Office, Plymouth (Sept. 20). A lecturer in botany at the Sunderland Technical College—The Chief Education Officer, Education Offices, 15 John Street, Sunderland (Sept. 22). Civilian education officers with a degree in engineering, in the R.A.F. Educational Service—The Secretary, Air Ministry, Gwydyr House, Whitehall, S.W.1 (Sept. 22). An assistant lecturer in mathematics at the University College of Swansea—The Registrar, University College, Singleton Park, Swansea (Sept. 24). An agricultural mycologist at the Agricultural Institute and Experimental Station, Kirton, Lincs—The Principal, Agricultural Institute, Kirton, near Boston, Lincs (Sept. 27). A senior lecturer in education in the University of Liverpool—The Registrar, The University, Liverpool (Sept. 30). A lecturer in chemistry in the Egyptian University, Cairo—The Dean of the Faculty of Science, Egyptian University, Abbassia, Cairo (Oct. 14). A professor of pathology at the Medical College, Vizagapatam, Madras—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (Nov. 3).

ERRATUM.—NATURE of Aug. 23, p. 272, col. 2, line 19, for "west to east" read "east to west".

Our Astronomical Column.

Meteoric Theory of the Lunar Craters.—*Scientia* for August contains a paper by A. C. Gifford in which he supports the meteoric origin of the lunar craters and walled plains, as against the volcanic theory. He refers to Meteor Crater in Arizona, and the gigantic Siberian meteor of June 30, 1908, as evidence that large meteoric masses still traverse the solar system; he assumes that they were much more numerous in the early days of the planetary system, since he adopts the planetesimal theory in preference to the gaseous filament theory proposed by Jeans and Jeffreys.

The objection that oblique impacts would not produce circular craters is answered by the assertion that the crater is not due to the impact itself, but to the explosion resulting from the violent heat produced by the sudden stoppage of the meteor. Mr. Gifford claims that the greater part of the matter scattered by the explosion would be driven out horizontally, forming the wall of the crater, while the matter that was thrown upwards would, on its descent, form the central peak or peaks. The explosion would reduce the material to fine powder, thus explaining the whiteness of many of the craters; it is noted that black glass appears white when finely powdered. Such matter as was reduced to a molten state by the impact would on solidification produce a dark surface, like that seen in the interior of Plato and other craters. The systems of radiating bright streaks surrounding Tycho, Copernicus, etc., are explained by supposing that in these cases the meteoric impact cracked the lunar crust, and molten matter was driven through the cracks from the interior, afterwards solidifying in a crystalline form.

Mr. Gifford compares his theory with that put forward in 1903 by Prof. N. S. Shaler. The latter also postulated the impact of large meteoric masses on the moon, but did not adopt the view that a great explosion would result from the sudden stoppage of the meteor and its reduction to a gaseous form; he supposed that the lunar surface would be liquefied and produce an extensive level region of a dark colour. In other words, he ascribed the *maria*, not the craters, to meteoric impact.

The Radcliffe Observatory and South Africa.—Mr. F. Robbins, the treasurer of the British Astronomical Association, has contributed two articles to the *Journal* of that body (vol. 40, Nos. 7 and 8) in which he describes the present general recognition of the value of South Africa as a centre for astronomical observation. This was pointed out by La Caille nearly two centuries ago; later on, Fallows and Sir John Herschel gave similar testimony. In the present century, Dr. Innes has spoken so enthusiastically of the climate of Johannesburg that astronomers from the United States, Leyden, and Berlin are establishing observatories in that region. The second article deals with the Radcliffe Observatory, the removal of which to Pretoria is now contemplated. John Radcliffe was a celebrated physician who died in 1714 at the age of sixty-one years. He left a large sum to be expended in Oxford. This is partly represented by the Library in the Radcliffe Camera. The remainder was devoted in 1770 to the building and endowment of the Radcliffe Observatory. The observations made by Dr. Hornsby, the first observer there, have not yet been fully reduced, but this is now being done by Dr. Knox Shaw. Mr. Robbins's article summarises the work done at the Observatory since its foundation, and includes eight reproductions of illustrations of the building and instruments.

Slitless Spectrograms of the Orion Nebula. In a recent communication to the Royal Astronomical Society (*Mon. Not.*, **90**, p. 580), Dr. W. J. S. Lockyer publishes some slitless spectrograms of the Orion nebula, extending from the green 'nebulium' lines to the pair at λ3727, obtained with much higher dispersion than has been previously used for this work. The results are discussed in relation to earlier work of the same kind by Pickering and Mitchell and to the researches of Keeler, Hartmann, and Reynolds, who photographed monochromatic images, using specially prepared light-filters. The results endorse in the main those of the investigators named, and show that the radiation from the central portion of the nebula—the so-called Huyghenian region—is almost entirely due to hydrogen, and the two 'nebulium' lines, N_{12}, now traced to O III. The 'Messierian' branch, to the east of the central portion, emits this radiation together with the λ3727 pair of O II, and the outlying regions radiate the λ3727 pair with practically nothing else. Numerical estimates are given, on an arbitrary scale, of the intensities of each of the several radiations in different regions. The relative faintness of the λ3727 images compared with those obtained by other workers—Reynolds, for example—is doubtless attributable to absorption in the lenses of the telescope; Reynolds, who obtained much stronger images, used a reflector. On p. 523 of the same volume of the *Monthly Notices* appears another communication from the Norman Lockyer Observatory—a further list of spectroscopic parallaxes and spectral types of *B*-type stars determined by Mr. D. L. Edwards. Data for 175 stars are tabulated and discussed in comparison with the results of other observers, with which they agree very well.

Research Items.

Medieval Indian Dress.—Mr. K. de B. Codrington contributes to the *Indian Antiquary* for August the first instalment of a study of medieval Indian culture as illustrated in the frescoes of the Ajanta Caves. The style of the frescoes, though mannered, is based on a minute observation of life; and there is no reason to doubt that the textiles, arms, and accoutrements are a faithful witness to vanished originals, except in the case of the frescoes of Buddha, of which the piled-up head-dresses and the jewelled necklaces never existed outside the tradition. With regard to chronology, four, or at most five, sequence styles can be detected, and the work is of the sixth and perhaps part of the seventh century, but certainly not later. Mr. Codrington here deals with costume and embroidery and textiles. It is usually said that cut and sewed garments were unknown in ancient India. Though this is borne out by the early sculpture at Bharhut and Sanchi, it does not apply to Ajanta. The indoor costume of the women consisted of a waist-cloth of varying length, usually supported by a beaded or jewelled belt. Occasionally a breast-cloth or scarf is worn. On other occasions a knee-length garment was worn, apparently slipped over the head, fitting tightly on the shoulders, and opening up on either side. With it was worn a long-sleeved waist-length bodice. The waist-cloth is the chief costume of the men, though the hunters and other forest people wear the small loin-cloth. A long-sleeved tunic to the knee is worn by soldiers and horsemen. Another type of jacket had short sleeves and ended at the waist. There are embroideries at the wrists, upper arm, and neck, and sometimes down the front. In some cases the dress seems to be a uniform. Here a waist-cloth is worn, but princes and heroes wear *paijamas* or tight-fitting 'jodhpurs'. With these one prince wears scarlet leather slippers.

Arterial System of Lemurs.—One of the most interesting results of the investigation of the anatomy of *Loris lyddekerianus* by Drs. A. Subba Rau and P. Krishna Rao (*Half-yearly Jour.*, Mysore University, vol. 4, p. 90, 1930) is the detailed description of a plexiform condition of the subclavian, external iliac, and middle sacral arteries. This leads to a general discussion of the purposes served by arterial plexuses, which, although most often found in aquatic air-breathing animals, are not confined to these and reveal no phylogenetic relationship or indeed at first sight any similarity of habit in their possessors. This is evident from their occurrence in creatures of such different modes of life as fishes, birds, and amongst mammals, ungulates, cetaceans, and lemurs. Various suggestions have been made as to the significance of the plexuses, such as that they merely represent a persistence of the embryonic phase of the arterial system, or that the minute branches diminished the velocity of the blood stream to the muscles, or that they served to maintain normal circulation during the period of contraction of the muscles. Judging from the structure and position of the plexuses in *Loris*, and from the association of venous with arterial plexuses, the authors "reaffirm the proposition already hinted at by Caralisle and add confirmative evidence in support of the view of Burne that these plexuses serve as storage tanks for arterial blood", and that they "regulate the supply of blood to the limbs in the same way as the spleen functions in regulating the blood supply to the viscera".

Aalborg Herring.—The Report of the Danish Biological Station to the Ministry of Shipping and Fisheries, **35**; 1929, by the Director, Dr. A. C. Johansen, contains some very interesting work. In the first part, "The Aalborg Herring and its Importance to the Danish Herring Fishery from the XVIth Century until the Present Day", Dr. Johansen deals with the history of the Limfjord herring fishery. In early years the Aalborg herring was the only one in the Limfjord, coming in from the Kattegat to spawn, but the breaking through of the Agger Isthmus in 1825 and the consequent inflow of salt water from the North Sea influenced the fishery profoundly. Not only was there an immigration of fish of different races from the west but also the altered conditions of salinity affected the spawning grounds of the original herring. There is distinct evidence to show that the eastern herring of the Limfjord of the present day is the descendant of the original Aalborg herring, having the same habits. Together with those of other races from different parts, it almost certainly spends part of its life in the Skagerrak feeding on the abundant and rich plankton to be found there, which fact accounts for its quality and its importance for centuries in the Danish fishery. The present day herring fishery, although proportionally not so large as in early years, is in a flourishing condition and the last decades show a decided increase, partly owing to the use made of the young, known as 'silding'.

Plankton of British Columbia.—Mr. G. H. Wailes has been occupying himself for some years with the marine plankton of British Columbia, publishing from time to time his very useful summaries of the various groups in the *Vancouver Museum and Art Notes*. The present paper, "Marine Zoo-Plankton of British Columbia" is reprinted from Vol. 4, 1929, of that publication, and embodies an address given to the Burrard Field Naturalists' Club on Oct. 25, 1929. The chief interest of this plankton lies in the fact that many forms are common to the Pacific and Atlantic and a plankton haul from Vancouver does not look very different from one from British seas. Some species are certainly different, but many may be closely related, such as *Calanus tonsus*, which to a large extent replaces *Calanus finmarchicus* in the Strait of Georgia. In the list of Copepoda are to be noted as abundant such common British species as *Calanus finmarchicus*, *Pseudocalanus elongatus*, *Metridia lucens*, and *Anomalocera pattersoni*, and similarly in other groups one meets many species which are familiar. A table is drawn up to show the food chains in the sea with special reference to *Clupea pallasi*, the Pacific herring, and the sock-eye salmon, *Oncorhynchus nerka*, including the various enemies of the latter fish.

Northern Echinoderms.—Two papers in *Bergens Museums Arbok* for 1929 deal with echinoderms. The first, by Mr. James A. Grieg, "Some Echinoderms from the South Shetlands" (Naturvidenskapelig rekke No. 3), describes some interesting collections from the Whaling Station in Admiralty Bay and from two of the whaling boats probably taken near the same locality. Among the sixteen species recorded there are some which are very little known and have only rarely been seen, and some which hitherto were only recorded from the Antarctic regions. In the second paper (No. 9) Mr. Sven Runnström describes a new spatangid larva from the west coast of Norway. These occurred between 50 and 100 metres, only four being found, representing a series of developing stages. The youngest larva still contained a good deal of yolk, showing that it must have come from a

yolk-laden egg. Red-gold yolky eggs were also collected which probably belonged to the same species. The author suggests that the eggs and larvæ are those of *Briaster fragilis*, the development of which was unknown but whose yolky eggs led Dr. Mortensen to predict direct development.

Mollusca from the Raised Beach at Portland Bill.—Collections have from time to time been made of the molluscan remains occurring in the raised beach at Portland Bill by such well-known observers as Pengelly, Prestwich, Damon, and Sykes, as well as by the Geological Survey, but so far no list has been given including the results of all their published observations. This has now been done by Mr. D. F. W. Baden-Powell (*Proc. Malac. Soc. Lond.*, Vol. 19), who has further added to the number of species found, which thus amounts to more than fifty, and supplied notes concerning each. With one possible exception, none of the forms is extinct, and the lower limit of age of the deposit may therefore be placed in the Pleistocene, and perhaps rather after the middle thereof, rather than in the Pliocene. The assemblage represents a more northern one than that now found at Portland, and the suggestion is that the sea at the time of the formation of this raised beach was colder than at present.

Temperature Gradients in the Permian of Texas.—W. B. Lang has discussed the depressed isogeothermal surfaces of the Permian Basin of Western Texas (*Jour. Wash. Acad. Sci.*, April 4, 1930). A well was recently drilled 4400 feet through Permian formations carrying anhydrite, into Carboniferous and Pre-Cambrian rocks. The subnormal gradient characteristic of the Basin was met with until the anhydrite beds were passed through, after which the gradient rapidly steepened. It therefore appears that internal heat is being conducted more rapidly by the anhydrite than by the underlying sediments. The thermal conductivities of anhydrite and rock salt are respectively 0·0123 and 0·0137, values twice as high as those characteristic of ordinary sediments. It is pointed out that our present data on the thermal conductivities of rocks as they exist under natural conditions are very meagre. The effects of compaction, porosity, bedding, mineral orientation, degree of cementation and water content have rarely been considered, although when cumulative they may be very great. There is urgent need for research on those lines, for until better data are forthcoming geothermal problems cannot be attacked with precision.

Copper Belt of Northern Rhodesia. The new copper field of Northern Rhodesia gives promise of becoming the greatest copper-mining centre of the world, for already the ore-reserves have been estimated at between 500 and 1000 million tons of copper. A detailed account by Alan M. Bateman of the deposits and their geological setting and origin appears in *Economic Geology*, June–July, 1930, pp. 365-418. The rocks of the area consist of an old basal complex overlain unconformably by the ore-containing Roan Series. The latter are continental sediments cut and metamorphosed by granite intrusions that represent the magmatic source of the copper. The areal distribution of the granite along the copper belt suggests a slightly eroded batholith with pendants of sediments projecting deeply into the granite. The pitchblende of Katanga has been shown by its lead ratio to be of late Pre-Cambrian age, and since the copper sulphides of Rhodesia and Katanga evidently belong to one metallogenic epoch, the Roan Series must therefore almost certainly be of Pre-Cambrian age. The sediments have been folded into open pitching folds with a north-westerly trend, giving V-shaped outcrops. The ore-beds are disseminations of minute specks of copper sulphides with sparse but deep oxidation in all the mines. The paragenesis is pyrite, linnæite, chalcopyrite, chalcopyrite and bornite, bornite, bornite and hypogene chalcocite, hypogene chalcocite, supergene chalcocite, and oxidation products. The latter probably formed at great depths during a former period of desert climate.

Wireless Echoes.—The address given by Prof. Carl Størmer to the Royal Society of Edinburgh on Feb. 17 has now been published in the Society's *Proceedings* (vol. 50, p. 187). He discusses the problem of whether the 'wireless echoes of long delay' come from space outside the moon's orbit or not. In a communication to NATURE of Jan. 5, 1929, he said: "the mathematical theory of the motion of electric corpuscles around a magnetised sphere shows that the chances of obtaining a well-defined toroidal space round the earth are good when the direction to the sun lies near the magnetic equatorial plane (perpendicular to the magnetic axis)." He predicted that it was very improbable that echoes would recur before the middle of February. This prediction was duly verified by several physicists. In particular, two observers in Indo-China observed two thousand echoes from a relatively small emitter station. The echoes came about 30 sec. after the signal and their amplitude was sometimes as great as one-third of the signal. Some of the experiments recorded prove conclusively that they were echoes. It seems as if the space outside the earth's orbit was traversed intermittently by very unstable streams of electrons. This may explain the great variety of echo times observed. It is also possible that multiple echoes may be caused by reflection between the inner walls of the toroidal space. The great variety of echoes is similar to the great variations in aurora phenomena and magnetic perturbations. If this explanation is correct, these wireless echoes give a striking proof of the corpuscular theory of aurora and a valuable method for exploring electron currents in cosmic space.

X-ray Wave-lengths and the Electronic Charge.—The determination of an X-ray wave-length by means of a ruled grating, in correlating quantities of atomic and of macroscopic dimensions, leads indirectly to an evaluation of the charge (e) on an electron, and, as is well known, the value of e obtained by this method is slightly larger than that found by the oil-drop method of Prof. Millikan. Further evidence for the reality of this discrepancy is furnished by some measurements of the wave-lengths of the L lines of molybdenum, of which an account is given by J. M. Cork in the second June issue of the *Physical Review*. The gratings used were of glass, ruled with either 30,000 or 14,400 lines to the inch, and were mounted in a vacuum spectrograph in direct connexion with a hot-filament X-ray tube. The values obtained for the wave-lengths of the $L\alpha_1$ and $L\beta_1$ lines were 5·4116 A. and 5·1832 A. respectively, whereas it was calculated on the basis of Prof. Siegbahn's measurements with a gypsum crystal that if calcite had been employed and corrections made for refraction, the two numbers would have been 5·3960 A. and 5·1674 A. The corresponding value for e is $4{\cdot}8162 \times 10^{-10}$ e.s.u., which is slightly larger than the number given by J. A. Bearden as a result of similar measurements with the K radiation of copper.

Cleavage Tests of Timber.—One of the tests made in connexion with the anisotropic properties of timber is a determination of its resistance to cleavage by the

application of equal and opposite loads, up to fracture, along the diameters of incomplete holes bored in flat specimens cut so that the stress is normal to the direction of the grain. An investigation by the photo-elastic method of the stresses which are set up, with the obvious limitation that the models used are isotropic, is described by Prof. E. G. Coker and G. P. Coleman in the *Proceedings of the Royal Society* for August. It has been found that the stresses are decidedly complex, and, moreover, that each form of test piece gives rise to a stress distribution peculiar to itself, which is doubtless further complicated in practice by the anisotropy, so that fairly comparable results in actual tests can only be expected when one form is adhered to. It is suggested, however, that it would probably be better to rely on a simple tension test to define cleavage property, with an arrangement so that load is applied uniformly and normally to the grain of the timber; such a test would, in a short length, exert normal tension across a large number of cells, and its selective action would ensure fracture at the weakest place.

Earthing Resistances.—The necessity of earthing electrical supply networks at one or more points has led engineers to study very carefully the best method of securing a good earthing electrode. In some cases a network of water pipes, the lead sheath of a large sized cable, or the steel structure of a building is available, but in many cases pipes, plates, and strips buried in the earth have to be used and it is advisable to know their relative merits. In a paper in the June number of the *Journal of the Institution of Electrical Engineers*, P. J. Higgs, of the National Physical Laboratory, gives a helpful account, both theoretical and experimental, of various kinds of earthing resistances. He begins by investigating the phenomena of polarisation and endosmose which happen when electric currents flow through damp earth and points out that their effects are very appreciable. Pipes, plates, and strips were installed in a plot of ground near the laboratory and periodic tests of their earth resistance were made for a year. The results obtained are of practical utility, but it is difficult to deduce general conclusions from them as the ground was probably far from being homogeneous. The seasonal variations in resistance during the year were found to depend on moisture and temperature, the former being the more important. The possible differences between measurements made with alternating and direct currents were also investigated. It was found that the resistances with direct current were greater than with alternating current, the maximum difference being about twenty per cent. The experiments indicate that pipes are the best to use. It was found that two pipes spaced about five feet apart and connected in parallel make a much more efficient earth than one pipe of diameter equal to the sum of the two.

Reactivity of Hot Coke.—It is known that the 'reactivity' or readiness with which a red-hot coke will reduce carbon dioxide is much increased by the presence of compounds of iron, and this 'reactivity' is liable to curious fluctuations with varying conditions. A study of this influence of iron compounds on the reactivity of coke forms the subject of a report by J. H. Jones, J. G. King, and F. S. Sinnatt (Fuel Research Technical Paper No. 25, H.M.S.O., 9*d*. net.) They show that the activating effect of metallic iron is large, of ferrous oxide small, and the fluctuations in activity are determined by the presence of iron in the reduced or reducible form. Should the iron be converted into non-reducible forms such as silicate or sulphide, the coke becomes relatively inert, although in the latter case reactivation may be brought about by exposure to air. Although other inorganic ingredients are known to increase the reactivity of cokes, it is concluded that in metallurgical cokes the preponderating catalytic effect is to be ascribed to the iron present.

Evolution of Heat by Polonium.—An interesting paper on this subject is published in the current issue of *Roczniki Chemji*, the organ of the Polish Chemical Society (**10**, 304-313; 1930), by Mlle. Alicja Dorabialska. The investigation was carried out in the Curie Radium Institute, Paris. The evolution of heat was measured by means of the adiabatic microcalorimeter constructed by Prof. Swietoslawski and Mlle. Dorabialska, made of different metals (copper, aluminium, zinc, nickel) and weighing only 2-3·5 gm. The experiments were made with three extremely small quantities of polonium, possessing an energy of about 3000 e.s.u. and weighing about 0·0005 gm., which were deposited one on a silver leaf, another on a nickel leaf, while a third was sealed in a copper tube filled with nitrogen. The rise of temperature amounted to 0·150°-0·250° per hour. The mean value obtained in the three series of experiments (nine in number) was $1·87 \times 10^{-5}$ ($\pm$ 0·9 p.c.) cal. per hour and per one electrostatic unit of polonium. From this number may be calculated the evolution of heat by one curie of polonium as 24·2 cal./hour. The number of α-particles calculated from this value would be equal to $3·4 \times 10^{10}$ per second either by one curie of polonium or by one gram of radium (Geiger and Werner find for this value $3·4 \times 10^{10}$). It is interesting to note that one gram of polonium would evolve $1·1 \times 10^{5}$ cal./hour, and one gram-atom of polonium would evolve during its life-time (197 days) $1·1 \times 10^{11}$ cal. (one hundred thousand million calories).

Sensitising and Desensitising Dyes of the Cyanine and Related Types.—A little more than two years ago (*Phot. Jour.*, 21; 1928) Mr. Olaf Bloch and Dr. Frances M. Hamer of the Research Laboratories of Ilford, Limited and of British Photographic Plates and Papers, Limited, published their first paper on the optical and photographic properties of these compounds, dealing with a complete series of typical, simple, cyanine dyes. They now (*Phot. Jour.*, 374; 1930) deal with 8 cyanine dyes, 12 styryl compounds, 2 cinnamylidene derivatives, and 10 anyls. Six of the cyanine dyes have recently been prepared for the first time by one of the authors. All were examined under the same conditions as described in the previous communication. Some of the compounds are sensitisers while others are desensitisers, but the change of structure which occasions this change of function is a comparatively slight one. The photographic action of dyes can show "enormous variations" with variations in the character and treatment of the emulsions employed in testing them, so that generalisations are at present impossible. The authors give the structural formulæ, names, spectrum absorption curves, sensitising curves, various physical properties, and certain analytical results of the dyes dealt with. During the discussion, Dr. Walter Clark suggested that it would be more reasonable to measure the absorption curve of the silver bromide dye complex rather than that of the dye itself, and Mr. Bloch said that it had been tried. He also asked if the authors had found any relation between the absorption spectrum of the desensitiser and the wave-length desensitisation due to it. Miss Hamer replied that there is no relation; there are numerous colourless desensitisers.

Denaturation of Proteins by Urea and Related Substances.*

By Sir F. GOWLAND HOPKINS, F.R.S.

UPON the facts enumerated the following simple method of determining the degree and rate of denaturation is based. A measured sample of the urea-protein mixture is diluted with ten times its bulk of water, and to secure complete precipitation of the denatured product a small quantity (say 1 gm. per 100 c.c.) of ammonium sulphate is added, and if precipitation is not immediate a small amount of acetic acid. When the precipitate has settled out it is filtered and washed, or better centrifuged and washed, until free from sulphate, when it will also be free from undenatured protein. The precipitate is then transferred to a tared basin, dried and weighed. The method is trustworthy and gives consistent results. If the protein left in solution after the precipitate has been removed be thrown out by saturation with ammonium sulphate, it will be found to be wholly soluble in water; that is to say, it is undenatured albumin.

The rate of denaturation increases with increasing concentration of urea. With respect to the influence of protein concentration but few determinations have been made, but it may be said that within a fairly wide range of concentration the percentage denatured in a given time by a particular concentration of urea remains of the same order.

The only quantitative results which will be given here are those which bear upon the effect of temperature upon the process. These have special interest. In the experiments carried out to determine the rate of change, solutions containing about 5 per cent of protein have been employed and the urea added to 60 per cent of full saturation (of saturation, that is, at 15° C.; 0·6 gm. added per c.c.). With such proportions, while denaturation is rapid, there is for relatively long periods no spontaneous separation of the product, either as precipitate or gel.

The following results of two experiments are fully representative of many. After the addition of urea the solutions stood at the temperatures mentioned, and the amount of denatured protein determined at the intervals stated. It is given in percentage of the whole protein present. The concentration of albumin mentioned in the first column is that of the original solution, not that present after the increase of volume due to the addition of urea.

Experiment.	Temperature. (° C.)	Amount of Denatured Protein at Intervals after Addition of Urea (per cent of whole Protein present).		
		15 Min.	1 Hour.	3 Hours.
Albumin solution 5 per cent	0	70·0	86·2	92·8
Urea, 0·6 gm. per c.c.	23	49·2	69·2	88·5
pH before dilution, 5·9	37	..	61·0	85·1
Albumin solution, 4·14 per cent	0	78·3	85·7	91·0
Urea, 0·6 gm. per c.c.	22	45·1	62·7	87·5
pH before dilution, 6·0	37	..	58·1	82·8

It is seen that denaturation by urea is a rapid process at each temperature investigated. While, however, heat denaturation was shown in the classical experiments of Chick and Martin[5] to be a process with an exceptionally high temperature coefficient, the above figures present the simulacrum of a negative coefficient. At the concentrations employed nearly 80 per cent of the albumin is denatured in 15 min. at 0° C. and less than 50 per cent at 22° C. Data such as the above have been repeatedly obtained. There is no reversal of the process on any lines with increase of temperature. Denaturation in any case ultimately proceeds nearly to completion. Only such temperatures are, of course, to be considered as are well below those at which heat denaturation itself begins.

The provisional hypothesis which perhaps most readily covers such facts is that denaturation occurs in a protein-urea compound which, save in the presence of large concentrations of urea, is highly dissociated, and of which the dissociation increases with rise of temperature sufficiently to account for the observed diminution in the rate of denaturation. The increased dissociation must then be assumed to outweigh other temperature effects. Proof or disproof of such a view must depend upon a study of various equilibrium relations. This offers technical difficulties and results are not yet available.

Certain substances, which can be shown to denaturate egg albumin, differ from urea in that their solutions exert little or no dispersive action upon the denatured product. Thus, whatever the relative concentrations, when such substances are present in amounts sufficient to denaturate actively, the product separates rapidly as a precipitate. Urethane presents a case of this kind.

If a concentrated solution of urethane be gradually added to an albumin solution, a point is reached at which precipitation begins immediately. If then the mixture be allowed to stand, denaturation and separation of the product proceed rapidly, and a large proportion of the protein will be denatured in the course of a few minutes. Thus to a 5 per cent albumin solution (pH 4·8) urethane in strong solution was added at 20° C. Precipitation began when the mixture contained 18 per cent urethane, and in ten minutes the precipitate (a typically denatured product) was centrifuged, washed, and weighed. It amounted to 59 per cent of the original protein. Like urea, concentrated urethane acts very rapidly at 0° C. It denaturates, though more slowly, when a solution contains 10 per cent or less.

Thiourea also denaturates while displaying little dispersive power. To separate samples of 4 per cent albumin solution at pH 4·86 thiourea was added to saturation (9 per cent). On standing at 17° C. precipitates separated and were weighed at successive intervals. After 15 minutes about 12 per cent, after 3 hours 25·5 per cent, 24 hours 62 per cent, and after 48 hours 80 per cent of the protein proved to be denatured.

Although the effective concentrations of the denaturants under discussion is high, it is scarcely likely that a 'lyotrope' action plays any dominant part in producing their effects. The phenomena differ of course in fundamental aspects from that of 'salting out' by electrolytes.

The simultaneous presence of electrolytes in solution, though, on the whole, tending to diminish its velocity, does not seem to exercise an important influence upon denaturation by urea, at least in the case of molar concentrations which alone have been tried. It is possible that a study of their effects in higher concentrations might throw some light upon the process.

One other circumstance associated with the phenomena under discussion should be mentioned. Using the green line of the mercury vapour lamp, the optical

* Continued from p. 380.

rotation of protein solutions was found to increase (after making due correction for the resultant change of volume) more than threefold when saturated with urea. In three separate experiments the rotation was increased to 3·25, 3·45, and 3·30 times its original value in water. I refer to this here merely as a fact empirically established.

SERUM PROTEINS.

Fewer observations have been made upon these and less space must be given to their description.

Attention must first be directed to the circumstance that blood proteins, unlike egg albumin, do not when denatured by any form of treatment yield a nitroprusside reaction direct. If, however, the denatured products are afterwards exposed to reducing agents, they then give a colour reaction which is intense. The most convenient method of demonstration is to add a small quantity of potassium cyanide to the solution of denatured protein, or to soak a precipitate or gel in a 1-2 per cent solution of cyanide before, in each case, dissolving a little solid nitroprusside in the fluid. A justifiable assumption is that the precursor of the active thiol group is a disulphide grouping not present in the native protein but established on denaturation. The effects of cyanide, etc., are exactly similar to those observed in the case of cystine and its conversion into cysteine.[6]

If native serum (horse or sheep) or solutions of separated albumin and paraglobulins be saturated with urea and the mixture allowed to stand for a few minutes in the presence of a little potassium cyanide, the addition of nitroprusside solution (plus ammonia if the solution be not sufficiently alkaline) will then produce an intense colour reaction.

Serum or its separated constituents (the behaviour of euglobulins has not been studied) on evaporation with denaturants on the lines described for egg albumin, whether the pH be that of native serum or reduced, say, to 5, behave similarly to the latter. Substances which denaturate the one protein act upon the other: those which fail in one case fail in all.

When, however, their behaviour is observed in solution, it becomes clear that the blood proteins are definitely more resistant to denaturation on these lines than in ovalbumin. It is noteworthy that the difference is more marked when the influence of urea, itself, is in question than in the case of, say, urethane with its smaller dispersive power.

Serum in its native condition or when brought to a pH of the order of 5, if saturated with urea, sets in a few hours at room temperature, and somewhat more rapidly at 37° C., to a jelly, and so in strong solutions do serum albumin and globulin. Such jellies treated as described above give an intense nitroprusside reaction, but only gradually after more prolonged standing do they show the resistance to redispersion into sols, which is characteristic of ovalbumin gels. Nevertheless, diluted serum or solutions of serum albumin or paraglobulin containing, say, 4-5 per cent protein, when mixed with such concentrations of urea as will rapidly denaturate ovalbumin, yield even after several hours' standing no precipitate on dilution or dialysis, and show no signs when dialysed free from urea of having assumed the characters of the suspensoid condition. This remains true if the pH of the solutions before or after adding the urea is brought to near the isoelectrical point of the proteins when denaturated by heat, 5·5·4. Observations giving these results have been made with the proteins of sheep's blood and with crystallised albumin from horse serum. Only after remaining many days in contact with urea do the blood proteins show evidence of more complete denaturation. On the other hand, their solutions when mixed with high concentrations of urea give at once after treatment with cyanide an intense nitroprusside reaction. It would seem as though these proteins undergo with readiness the chemical changes which in all cases are associated with denaturation, but the colloid particles of the product are more resistant than those of egg albumin to the dehydration which characterises the change from the lyophil to the lyophobe condition.

Easily to be demonstrated, however, is the denaturation of blood proteins under the influence of urethane, especially, but not only, when they are brought near to their isoelectric point. The following figures are illustrative. Dialysed and filtered sheep serum was brought to pH 4·86 and urethane (0·3 gm. per c.c.) added. After 1 hour at 20° C. 22·5 per cent of the total protein was denaturated; and after 3 hours 41·0 per cent. With thrice the concentration of urethane 43·5 per cent was denaturated in 1 hour. The process is clearly much slower than in the case of ovalbumin.

It is with intention that these notes have been confined to a simple description of observations which are themselves of a preliminary kind. Points of theoretical interest can scarcely fail to be noted, but at present they lack quantitative investigation. It has seemed worth while to give this indication that the phenomena in question are worthy of such investigation. Certain quantitative studies are being made in the Cambridge School of Biochemistry.

Imperial Horticultural Conference.

AN Imperial Horticultural Conference, arranged by the Imperial Bureau of Fruit Production, met at the house of the Royal Society of Arts on Aug. 5-7.

The papers presented to the Conference were grouped according to the aspect of horticultural work discussed. In the group dealing with field experimentation, Mr. T. N. Hoblyn, of East Malling, stated that the failure of earlier research on fruit trees was due to (1) the inherent variability in the trees themselves, (2) variation due to outside causes. These causes of error can now be eliminated by the adaptation of statistical method to known material raised clonally. Prof. E. E. Cheesman, Imperial College of Tropical Agriculture, Trinidad, stated that the same inherent variability is markedly noticeable in tropical crops, which are largely cross fertilised and heterozygous. Here, too, in dicotyledons, clonal propagation seems to offer a solution; cacao is at present under investigation at the Imperial College at Trinidad. In the subsequent discussion, emphasis was laid on the desirability of close contact between the statistician and the horticultural worker, and on the importance of the close observation of individual trees in horticultural experiments.

Dealing with the application of the pure sciences to horticultural problems, Prof. B. T. P. Barker, Long Ashton Research Station, Bristol, remarked that chemistry can help the cider industry, particularly by determining the constituents of the apple; apples other than pure cider varieties can be used to supplement these. Investigations are in progress on the substitution of centrifuging for filtering. Prof. V. H. Blackman, Imperial College of Science and Technology, London, said that the physiological study

of the effect of external conditions on horticultural crops is complicated by the interrelationship of various factors. The solution of the stock-scion problem may possibly lie in some balance of processes, for example, enzymic action, or of ratio of assimilation to respiration.

The discussion of methods of fruit storage occupied the whole of the final session. Dr. Franklin Kidd, Low Temperature Research Station, Cambridge, divides the problems into two groups: (1) those concerned with reduction of wastage and improvement of quality, using present methods; (2) those connected with the evolution of new methods. Local testing of storage qualities is desirable, as is also investigations into trade practice in handling between producer and consumer. The effects of numerous volatile substances in the atmospheres of stores need further investigation. Dr. A. Horne, Imperial College of Science and Technology, London, dealt with the infection and invasion of the apple fruit by fungi and their effect on storage quality. The presence of high fungal numbers and many pathogenic forms in an orchard are in certain cases associated with considerable wastage under ordinary storage conditions, and low numbers and few pathogenic forms with little wastage. Resistance to invasion differs greatly. Miss H. K. Archbold, also of the Imperial College of Science and Technology, showed that prolonged storage life of the apple is generally associated with a slow rate of loss of oxidisable material in respiration. Time of picking greatly influences the chemical composition and hence the storage qualities of the apple. Mr. R. G. Tomkins, Low Temperature Research Station, Cambridge, discussed the biological effect of atmospheric humidity on fruit in storage, noting its possible success in checking certain rots, its value in prolonging storage life, and the practical difficulties met. Mr. Meirion Thomas, Armstrong College, Newcastle, described the condition known as 'aldehyde poisoning'; this condition can be distinguished from brown heart by chemical analysis. The problem is proving to be of considerable economic importance.

The papers presented to the Conference will be published in full by the Imperial Bureau of Fruit Production.

The Egyptian Lily.

IN *Ancient Egypt* for September 1929 (2nd ed.), recently issued, Sir Flinders Petrie publishes the result of a comparison of some two thousand dated and placed examples of the use of the lily in decorative art. The study was undertaken with the view of demonstrating that decoration being arbitrary, unlike objects of utility which may be invented and reinvented any number of times, in its resemblances it is of great value as an indicator of the movements of trade, of culture, of conquest, and of race. The comparative study of decoration thus gives an organised method of research into ages which are without a record.

The lily motive seems to have originated in Crete. It is used in Middle Minoan III. about 2300 B.C. on the great jars of Knossos and on fresco. It was here a natural group; but by about 1600 B.C. it was modified. It appears in late Helladic of about the same time, and with a less natural form about 1400 B.C. There is a form in Rhodes which suggests that the plant was not well known there. The Cretan form passed into being merely a flower; but in Egypt it became fixed in its botanical aspect of the parts, and this permanent type went through immense changes. The detail is much more precise than on the Egyptian paintings.

In various examples different types of simplification are shown. In Hauran the different parts are maintained, but they are wildly changed in an example from Cyprus. In Persia the tips of the spathe become a bunch of dates. An Italian form at Vulci brought in sprays, and such a form passed to India, where calyx and spathe survived. A curious bowl form, proved by examination of transition forms to be the Assyrian form borrowed from the Hittite, was borrowed by Cyprus, where again the old parts were put together differently on the top of an Ionic column of Assyrian origin. A bowl pattern was brought from Cyprus or North Syria into Italy, and two patterns which can scarcely be separated from this stage turn up at Athens and Mathura, India. An inverted form appears to be a Phœnician importation into southern Etruria.

When the form was used either way up, there was more licence in the employment of leafage. Of this type a derivation appears in northern pre-Roman France, which thus must be the result of trade. The Italian form passed back to Crete. In classical times various forms are found about Rome, and by trade passed to India, appearing in the caves of Ajunta. Later still it survived at Ravenna and was worn out finally in the eighth century at Rome and at Cividale. Thus the lily as a decorative motive originated in Crete before 2000 B.C.; coming thence to Egypt it passed by 1400 B.C. to the Hittites and on to Assyria as a tree pattern. Thence transformed by ignorance it reached Cyprus and so came by Phœnician trade to the Tiber, and spread northwards from Rome, naturalised in Italy as a foliage form and finally a group of relief.

Historic Natural Events.

Sept. 8, 1900. Galveston Hurricane.—The hurricane of Sept. 1-12, 1900, is described as the most severe storm which ever occurred in the United States. After travelling westward south of Haiti, it curved to the north across Cuba and nearly to Florida. There it turned again to the west-north-west, and growing in intensity, struck the coast of the United States near Galveston on Sept. 8, after which it passed inland and rapidly broke up. Galveston is built on a low sandy island about thirty miles in length and two to three miles in width, and the city was completely wrecked. The anemometer recorded a velocity of 100 miles an hour when it was blown away at 2 P.M., but the velocity increased steadily until 8 P.M., at which time the corrected barometer reading was 963 mb. (28·44 in.). The storm raised the level of the sea by 15-20 feet, and the whole island was flooded. Nearly half the houses were completely destroyed by wind and sea, more than 6000 people were killed, and property to the extent of 30 million dollars was lost. Enormous losses of life and property were also reported from the coast of the mainland, but owing to the Weather Bureau warnings, only two ships were lost.

Sept. 9, 1897. Typhoon in Sea of Japan.—A violent typhoon travelled along the east coast of Japan, causing enormous damage. At Tokyo the wind reached a velocity of 128 miles per hour in squalls from the south. Many ships were lost; on land many houses were blown down, but the greatest damage was done by the typhoon wave, which flooded large areas and more than 5000 houses.

Sept. 10-13, 1898. West Indian Hurricane.—A violent hurricane passed just south of Barbados on the evening of Sept. 10, crossed St. Vincent on the morning of Sept. 11, and continuing northwards,

passed east of Sombrero on Sept. 13. On Barbados 11,400 houses were swept away, about 115 lives lost, and 50,000 people rendered homeless. On St. Vincent, which experienced the full force of the storm, every exposed building or tree was blown down and 200 lives were lost. The rain was very heavy, amounting to 4·95 in. between 9 A.M. and noon on Sept. 11; probably as much fell between noon and 3 P.M., but the raingauge was destroyed. The rain filled the mountain torrents and whole villages were swept away. All shipping was destroyed. At St. Lucia an avalanche filled a valley for 3 miles, burying houses and estates. A curiosity of the storm was that at Kingstown, St. Vincent, the rain which fell was hot and stinking, and rotted clothes exposed to it; it may have come from the crater lake of Soufrière.

Sept. 10, 1899. Alaskan Earthquake.—This was one of the world's great earthquakes, for it disturbed an area of perhaps $1\frac{1}{2}$ million square miles. At the time little was known about the earthquake, for the central district was almost uninhabited. Six years later, however, the evidence of remarkable changes of elevation was still visible in raised beaches and in the bands of dead barnacles adhering to the cliffs. These showed that the coast was uplifted from a few feet to 47 ft. 4 in. Variations in the amount of elevation revealed the existence of a number of faults that divided the crust up into blocks, the tilting of which gave rise to the earthquake.

Sept. 10, 1902. Hailstorm near Maidstone.—Great damage was caused to the hop-crop in the districts around Maidstone by a violent hailstorm, accompanied by thunder. The hail in many places stripped the plants of all foliage, and the heavy rain even washed away the poles.

Sept. 10, 1903. Gale over British Isles.—During the evening and night of Sept. 10 a deep barometric depression passed rapidly across Ireland and northern England. In its front the barometer fell at the rate of nearly 5 mb. (1·4 in.) an hour, and pressure in the centre was so low as 975 mb. (28·8 in.). On the south coast of England the gale had a remarkable effect on the autumn vegetation, which was scorched brown, curled, and shrivelled up, even at places in the lee of the downs, several miles inland. This effect can scarcely have been caused by salt spray, as the storm was accompanied by very heavy rainfall.

Sept. 11, 1806. Hurricane in Porto Rico.—One of the severest hurricanes on record in the southern part of the island of Porto Rico occurred on this date. Many churches and a large portion of the houses were damaged, fruit trees were destroyed, and rivers overflowed their banks, destroying much property. At San Juan shipping suffered much loss.

Sept. 12, 1717. Triolet Glacier Outbreak.—A great moraine at the end of the glacier of Triolet, at the bottom of Val Ferret, broke up in the night, and an immense amount of débris, mixed with water and enormous blocks of ice, covered all the ground surrounding two châlets. Since then the fertile plain on which these châlets were situated has been covered by ice.

Sept. 13, 1922. Highest Recorded Temperature.—At Azizia in the semi-desert plain of Jefara, in northern Africa, between the coast of Tripolitania and the interior plateau, a maximum temperature of 136·4° F. was recorded on Sept. 13, 1922. This is the highest shade temperature ever recorded by a tested thermometer exposed under standard conditions, and is 2·3° F. higher than the previous record at Death Valley, California on July 13, 1910. The site of the station is in a shallow basin which becomes highly heated by the sun's rays.

Societies and Academies.

PARIS.

Academy of Sciences, July 16.—The president announced the death of A. T. Schlœsing, member of the Section of Rural Economy.—**Ch. Maurain, Mlle. G. Homery, and G. Gibault**: The vertical atmospheric current. At the Val-Joyeux Observatory the electric field is measured continuously and the conductivities corresponding to the positive and negative ions measured three times daily. Tables are given showing the values of the vertical currents deduced from these data.—**J. Courrègelongue and H. Maugein**: Some experiments on auto-oscillation and autorotation of immersed plates.—**Edgar Pierre Tawil**: Stationary ultra-sonorous waves made visible in gases by the method of striæ. A description of an apparatus capable of rendering visible the stationary waves produced in air by a piezo-electric crystal. Photographs are given.—**Herculano de Carvalho**: The presence of uranium in mineral waters. The uranium-radium ratio. Uranium determinations have been made in waters from five springs, the amount found being of the order of 10^{-6} gm. per litre. There was no constant ratio between radium and uranium.—**F. Bourion and Mlle O. Hun**: The determination by the boiling method of the affinity relative to the formation of the complex ammonium iodide-cadmium iodide.—**Auméras and Tamisier**: The spectrophotometric study of the cupripyridine ion in aqueous solution.—**Mme. Ramart-Lucas and J. Hoch**: The configuration of molecules in space. The absorption in the ultra-violet of the acids $C_6H_5(CH_2)_n.CO.OH$, $C_6H_5(CH_2)_n.(CO.OH)_2$ and the hydrocarbons $C_6H_5(CH_2)_nC_6H_5$.—**Sébastien Sabetay and Jean Bleger**: The chromic oxidation of the cyclanepolyols. By the oxidation of quinite in acetic anhydride solution by chromic anhydride, cyclohexandione is obtained in good yield (56 per cent theoretical yield): its physical properties and chemical reactions are given.—**Charles Dufraisse and Marius Badoche**: Researches on the dissociable organic oxides: the transformation of oxyrubrene into a non-dissociable isomer, iso-oxyrubrene. A probable formula is assigned to this oxide, but it is still difficult to suggest a formula for oxyrubrene which explains its property of dissociation with liberation of oxygen.—**Marcel Solignac**: The mineralogical characters of the oolitic iron mineral of Djebel el Ank, southern Tunis.—**Jean Lugeon**: Measurements of the ionisation, of the electric field, and of atmospherics on Mt. Blanc.

CRACOW.

Polish Academy of Science and Letters, June 2.—**C. Zakrzewski and D. Doborzynski**: Some remarks on the dielectric polarisation of the elements. The dielectric polarisation of elements not belonging to the seventh group of the periodic system is independent of the temperature, and the molecules of these elements do not possess electric dipoles. The polarisation of elements belonging to the seventh periodic group depends on the temperature, and this polarisation can be expressed by the well-known Debye formula.—**Wlad. Gorczyński**: The maximum values of the intensity of the solar radiation observed on oceans and in other regions of the earth. Whilst the ocean values do not exceed 1·4 cal. at normal incidence, 1·4–1·5 cal. is obtained on the plains and 1·7 cal. in an oasis of the Sahara. Still higher maxima are observed at high altitudes.—**H. Lachs and J. Biczyk**: The determination of the electrokinetic potential with the aid of the method of the e.m.f. of filtration.—**E. Chrobaczek**: The phenomena of correlation in

wheat and the theory of associations in chromosomes. —**A. Oszacki**: The oxygen in the venous blood of human sarcoma.

SYDNEY.

Linnean Society of New South Wales, June 25.—**J. R. Malloch**: Notes on Australian Diptera (24). This paper completes the notes on Tachinidæ. Species belonging to the tribes Actiini, Linnæmyiini, Cylindromyiini, and Tachinini are dealt with. Twelve genera, one subgenus, and forty-six species are described as new, and a new name is suggested for *Phorocerosoma*, preoccupied.—**G. H. Hardy**: Fifth contribution towards a new classification of Australian Asilidæ. This paper revises the tribes Saropogonini and Stichopogonini, contrasting the Australian forms with many of the world's genera. One new genus and two new species are proposed; a table of chætotaxy, and a key to the genera are included.—**H. N. Dixon** and **W. Greenwood**: The mosses of Fiji. The mosses known from Fiji now total 205 species, about half of these having been added to the list since 1917 by the collections made by one of the authors (W. G.). This paper contains record of all the known species in Fiji, with notes of the localities from which the species have been collected. A key is given to the genera found; twenty-seven species and five varieties are described as new.

ROME.

Royal National Academy of the Lincei, April 6.—**V. Volterra**: Hereditary mechanics. The energetics of hereditary mechanics, limited to the case of linear hereditary actions, was recently considered. The case of non-linear actions for a system with only one degree of freedom is now treated.—**T. Levi-Civita**: Further consideration of the motion of a body of variable mass.—**G. Hagen**: Photographed oscillations of the free pendulum.—**F. Vercelli**: General method for the analysis of the periodicities in statistical and experimental diagrams.—**G. Silva**: The formula of normal gravity.—**G. Tizzoni** and **G. De Angelis**: Immunity against the adeno-carcinoma of the mouse conferred by the pulp of the tumour itself with addition of formol. The phenolated vaccine previously tried causes mainly an anti-neoplastic immunity, whereas the formolated vaccine results principally in anti-toxic immunity.—**A. M. Bedarida**: The infinity of prime numbers in quadratic forms. **G. Barba**: The functional equation $f(x)f^1(x)=f[f(x)]$ connected with a geometrical problem. The form of the intrinsic equation of a curve in order that this may be similar to its evolute, is considered.—**P. Cattaneo**: A class of cyclic varieties.—**I. J. Schwatt**: The development of $\sec^p x$ in Maclaurin's series.—**A. Belluigi**: The topographical corrections in Eötvös remainders. **E. Segrè**: Statistical calculation of the spectrum of an ionised atom. The statistical method is applicable to the construction of the spectrum of an ionised atom from the atomic number and the degree of ionisation. Even with highly ionised atoms the method furnishes satisfactory results.—**G. Bargellini** and **A. Grippa**: 2 : 5 Dibromoanisidine. This compound and several of its derivatives are described.—**G. Bargellini** and **F. Madesani**: 3 : 5- and 2 : 6-Dibromoanisidines. Bromination of acetyl-*p*-anisidine yields the acetyl derivative, not of 3 : 5-, but of 2 : 5-dibromoanisidine.
G. Natta: Crystalline structures of hydrogen sulphide and hydrogen selenide (1). X-ray investigation indicates that hydrogen sulphide and hydrogen selenide crystallise in the cubic system. For the former, the side of the unit cell is $5 \cdot 778 \pm 0 \cdot 003$ A. and its volume $192 \cdot 9 \times 10^{-24}$ c.c. On the assumption that the unit cell contains four molecules and that the weight of the hydrogen atom is $1 \cdot 65 \times 10^{-24}$ gm., the density of solid hydrogen sulphide at $-170°$ is calculated to be $1 \cdot 166$.—**G. A. Barbieri**: Reduction of silver ferricyanide by means of ferrous sulphate. Under suitable conditions, ferrous ions may reduce ferricyanogen ions, even in acid solution. This reaction is applicable to the determination of ferricyanides.—**S. Visco**: Action of the latex of *Ficus carica* on proteins. The action of this latex on the proteins constituting the albumen of hens' eggs does not proceed beyond the formation of products of the character of secondary proteoses.—**S. Sorrentino**: The older formations of Monte S. Calogero and of Nadure near Sciacca.—**L. Maddalena**: Study of a phenomenon exhibited by the Aurisina stone used for covering walls. When this stone is used for outside constructional work, yellowish rusty spots, often zoned, gradually develop on it, and, after increasing in diameter to 15-20 cm., slowly fade and finally almost disappear. This phenomenon is due to the formation of colloidal iron hydroxide (hydrosol) by the oxidation of the pyrites present to ferrous sulphate and interaction of this with the lime of the mortar in presence of slightly alkaline water. Moisture easily transports the colloid to the outer surface of the porous stone, where it is first fixed as hydrogel by evaporation of the water and later washed away by the mechanical action of rain.—**C. Artom**: Origin and evolution of parthogenesis in *Artemia salina diploide* of Cette. **P. Pasquini** and **G. Meldolesi**: Investigations on radio-sensitivity in the development of the eggs of amphibia (2). Specific alterations and secondary malformations from differential radio-susceptibility in *Rana esculenta*.—**N. A. Barbieri**: Improvement in the metabolism of plants by physiological culture without alteration of the soil. Experiments with *Cattleya*, maize, beans, potatoes, sugar-beet, etc., confirm the advantages of the author's method of homogeneous mineral culture, which consists of localised application of a mixture of the soluble and insoluble salts existing preformed in the plants in the amount required by the whole of the crop.—**V. Rivera**: Radiation and growth in plants—development under a leaden screen.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, Vol. 16, No. 5, May 15).—**A. E. Navez**: On the distribution of tabular roots in *Ceiba* (Bombacaceæ). In Cuba, the so-called buttress or tabular roots of these trees grow principally on the sides struck by the dominant winds, the largest generally in the N.E.-E.N.E. direction. The roots are 'resistance cables' rather than 'buttresses'.—**Ernest Glen Wever** and **Charles W. Bray**: Action currents in the auditory nerve in response to acoustical stimulation. A decerebrated cat was used and electrodes placed on the exposed auditory nerve. Sound stimuli applied to the animal's ear set up action currents which, when amplified, produced sounds in a telephone apparently identical with the original stimulus. Speech was transmitted with great fidelity; response was obtained with frequencies between 125 and 4100 ~ per second. Frequency of response is correlated with frequency of stimulation. —**Robert K. Nabours**: Mutations and allelomorphism in the grouse locusts (Tettigidæ, Orthoptera). —**F. H. Murray**: The electromagnetic field exterior to a system of perfectly reflecting surfaces. A mathematical discussion.—**Louis S. Kassel**: The rates of second-order gas reactions. A theoretical discussion based on the assumption that the chance of reaction at a collision increases with energy of collision.—**Ernest W. Brown**: On the prediction of trans-Neptunian planets from the perturbations of Uranus. —**Edwin H. Hall**: The 'reaction-isochore' equation

for ionisation within metals.—**Sinclair Smith**: The effect of low temperatures on the sensitivity of radiometers. Radiometers in hydrogen, helium, and air in a specially designed chamber at $-180°$ C. were exposed to light from a controlled source. Maximum sensitivity increases at low temperature and shifts towards lower pressures.

CONGRESSES.

SEPTEMBER 3 TO 10.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Bristol). (*For particulars see* NATURE *of Aug. 30.*)

Change of Programme.—(B) *Sept.* 9, at 11 A.M.—Prof. C. S. Gibson and Prof. J. L. Simonsen: Some Recent Investigations of Organic Compounds of Gold; instead of Prof. Semenoff: The Initiation of Combustion.

SEPTEMBER 4 TO 14.

INTERNATIONAL ZOOLOGICAL CONGRESS (at Padua).

SEPTEMBER 7 TO 13.

INTERNATIONAL CONGRESS OF AMERICANISTS (at Hamburg).—Papers on The Aboriginal Peoples of America and their Ethnic Relations, The Prehistory of America, Manners and Customs of the Various Groups of Indians and their Distribution in the Old and New World, The Aboriginal Languages, The Discovery and Colonisation of America, The Geography and Geology of America, with Special Reference to Human Activities, and a Discussion on The Civilisation of the Indians at the time of their first contact with Europeans and to-day.

SEPTEMBER 8 TO 12.

INTERNATIONAL CONFERENCE OF THE APIS CLUB.

Monday, Sept. 8 (at Apothecaries' Hall, Water Lane, E.C.), at 3.30.—Miss Annie D. Betts: The National Importance of Apiculture (Presidential Address).

Wednesday, Sept. 10 (at Crystal Palace).—Dr. G. Morison: Notes on Acarine Disease.

Thursday, Sept. 11 (at Crystal Palace), at 11 A.M.—Dr. H. W. de Boer: Behaviour of Diastatic Ferments in Honey when Heated.

At 12 noon.—C. H. Hooper: Fruit Pollination and the Importance of Insect Visitors in Fruit Production.

At 2.30.—D. Morland: Frosting.

At 5.30.—Dr. F. Kretschy: Our Bee as Doctor.

At 6.30.—L. M. Bertholf: The Distribution of Stimulative Efficiency in the Ultra-Violet for the Honey Bee.

Friday, Sept. 12 (at Crystal Palace), at 11 A.M.—M. le Chanoine A. Delaigues: Transformism.

At 12 noon.—Dr. J. Stitz: Ultra-Violet Absorption of Honey.

SEPTEMBER 9 TO 12.

INSTITUTE OF METALS (at Southampton).

Tuesday, Sept. 9 (in Chantry Hall), at 8 P.M.—Prof. D. Hanson: The Use of Non-Ferrous Metals in the Aeronautical Industry (Autumn Lecture).

Wednesday, Sept. 10 (in Chantry Hall), at 10 A.M.—E. A. Smith: Rolled Gold: Its Origin and Development.

Dr. W. Rosenhain, J. D. Grogan, and T. H. Schofield: Gas Removal and Grain Refinement of Aluminium Alloys.

J. D. Grogan: Pressure Die-Cast Aluminium Alloy Test-Pieces.

N. W. Ageew and Olga I. Vher: The Diffusion of Aluminium into Iron.

Dr. K. L. Meissner: The Artificial Ageing of Duralumin and Super-Duralumin.

Dr. W. L. Fink and Dr. K. R. Von Horn: Lattice Distortion as a Factor in the Hardening of Metals.

Dr. Marie L. Gayler: A Study of the Relation between Macro- and Microstructure in Some Non-Ferrous Alloys.

Thursday, Sept. 11 (in Chantry Hall), at 10 A.M.—Dr. J. C. Hudson: The Effect of Two Years' Atmospheric Exposure on the Breaking Load of Hard-Drawn Non-Ferrous Wires.

Dr. W. H. J. Vernon and L. Whitby: The Open-Air Corrosion of Copper. Part II. The Mineralogical Relationships of Corrosion Products.

Dr. E. Voce: Silicon-Copper Alloys and Silicon-Manganese-Copper Alloys.

E. Vaders: A New Silicon-Zinc-Copper Alloy.

H. C. Dews: The Effects of Phosphorus on the Strength of Admiralty Gun-Metal.

Dr. D. Stockdale: A Note on the Constitution of the Cadmium-Zinc Alloys.

Prof. G. Tammann: On the Determination of Crystallite Orientation.

D. A. N. Sandifer: Pendulum Hardness Tests of Commercially Pure Metals.

F. Hargreaves: Heat-Treatment, Ball-Hardness, and Allotropy of Lead.

SEPTEMBER 11 TO 14.

SWISS SOCIETY OF NATURAL SCIENCES (at St. Gallen).—In sixteen sections covering Pure and Applied Science and Medicine. Addresses by Prof. E. Abderhalden, on The Significance and Mechanism of Ferments in Nature; Prof. P. Niggli, on Ten Years' Work of a Mineralogical and Petrographic Institute; Prof. R. Chodat, on The Symbiosis of Lichens and the Problem of Specificity; and Prof. C. Wegelin, on Endemic Cretinism.

SEPTEMBER 13 TO 20.

NEWCOMEN SOCIETY FOR THE STUDY OF THE HISTORY OF ENGINEERING AND TECHNOLOGY (at Liverpool).

SEPTEMBER 15 TO 20.

IRON AND STEEL INSTITUTE (in Czechoslovakia).

Monday, Sept. 15, at 10 A.M.—A. Kříž: The Heterogeneity of an Ingot made by the Harmet Process.

J. Šárek: What Reasons Compelled the Prague Ironworks to Introduce Thin-Walled Blast-Furnaces.

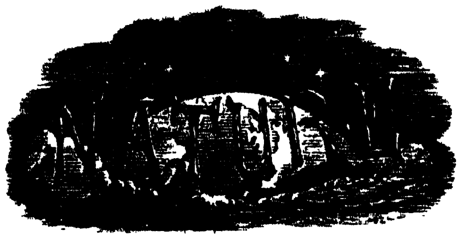
W. H. Hatfield: Permanence of Dimensions under Stress at Elevated Temperatures.

Tuesday, Sept. 16, at 10 A.M.—O. Quadrat: A Contribution on the Problem of the Analysis of Basic Slags and the Representation of their Composition in a Triangular Diagram.

H. C. Wood: Open-Hearth Furnace Steelworks. A Comparison of British and Continental Installations and Practice.

D. F. Campbell: High-Frequency Steel Furnaces.

L. W. Schuster: The Effect of Contamination by Nitrogen on the Structure of Electric Welds.



SATURDAY, SEPTEMBER 13, 1930.

Fertilisers and Soil Fertility.

THE extent to which the phosphatic fertilisers have dominated the outlook of farmers all the world over is well seen by the fact that when a country first embarks upon anything approaching a large scale use of artificial manures, it is the phosphatic fertilisers that are almost invariably employed, to the practical exclusion of all others. This is understandable, and within certain limits entirely reasonable: for when rainfall and sunshine are adequate, and where leguminous plants can thrive abundantly, a deficiency in phosphates is often the sole limiting factor to greatly increased production, and under these conditions phosphates frequently occasion results of such a pleasing magnitude that the farmer is, perhaps naturally, not in a hurry to look for methods of still further increasing his productivity—although, of course, it seldom happens that the addition of phosphates is all that is necessary to produce the highest yields obtainable.

Thus, for example, in a pastoral country like New Zealand, in the main with abundant rainfall and conditions potentially favourable for the spread of leguminous plants, the benefits from phosphatic manures have been enormous, and the increase in their use during the last decade very remarkable; while in the case of those areas in the wheat belts of Australia where the methods of fallow practices have been perfected and water conserved to the maximum, it has been found remunerative to increase the dressing of superphosphate very appreciably above the amounts that were originally considered adequate.

The position of South Africa (the Union and Southern Rhodesia) is perhaps unique, and agriculturists—not only of that continent, but also of the world at large—should derive inspiration from Sir Frederick Keeble's critical survey* of the fertiliser position, part of which appears elsewhere in this issue (p. 417), and more particularly from the penetrating suggestions he makes as to the problems which South Africa sets the scientific investigator for solution.

Sir Frederick has had the advantage of studying extreme conditions. In South Africa, as he tells us, not only are enormous tracts subject to slight precipitation, but also mineral deficiency is universa —and, we might add, leguminous plants are not abundant, for there, unlike New Zealand, wild white clover has not run riot, and, unlike large

* "Agricultural Problems in South Africa." Paper read before Section M (Agriculture) of the British Association at Bristol on Sept. 5

areas in Australia, a host of little European annual clovers have not become tantamount to wild plants. What are the limiting factors to a satisfactory scale of production in South Africa? This is the question Sir Frederick has set himself, if not to answer, at least to explore; not, he thinks, by any means necessarily the scant precipitation, but rather the inherent deficiency in plant foods—first and foremost an acute deficiency in phosphates and in lime, and secondly, a deficiency in nitrogen.

From the point of view of grassland, the effects of drought are no doubt greatly accentuated by the prevailing mineral deficiency, which must tend to stunt even the native vegetation and render colonisation by a more desirable and nutritious flora impossible, and in this connexion it is probable that a scarcity of available nitrogen must rank with a scarcity of phosphates as a contributing factor of no mean importance. That this is indeed the case is rendered the more likely from the results of experiments recently conducted in Great Britain, which have shown that in dry seasons it is the pastures manured with a complete and well-balanced combination of fertilisers that not only maintain the highest productivity, but also suffer the least damage. It is significant, too, and corroboratory, so far as it goes, of Sir Frederick's far-reaching thesis, that it is scarcity of plant food rather than of water that is the outstanding cause of low productivity in South Africa; that experiments with which we have been concerned on soils of very low fertility have shown that the difference between success and failure in the establishment of new sward-forming plants, through the intermediary of seeds, may turn upon the application of a complete and well-balanced manurial dressing at or a little before sowing. Sir Frederick adduces cogent reasons in support of his view that the South African grasslands are not only on the face of it likely to be, but also in fact are, nitrogen-starved; and by reference to small-scale experiments conducted by Mr. T. D. Hall, shows that these grasslands, despite the inherent deficiency in phosphates, none the less show a remarkable response to ammonium sulphate when applied by itself—the response, however, being greater when the added nitrogen (in sufficient quantity) is supported by phosphates, and greater still when supported by phosphates and lime.

The position that clovers may possibly be made to take in the improvement of South African grasslands, in our view, therefore, deserves greater emphasis. White clover, for example, is by no means unknown in the Union, and it is more than probable that by sowing the seed in conjunction with heavy phosphating this all-valuable pasture plant, or for that matter some kindred legume, might be established on a telling scale, and consequently we should like to see added to the experiments and researches that Sir Frederick suggests, trials with a large number of species and strains of leguminous plants; but further than this, such trials should in all cases be supported by inoculation, for it is more than probable that the organism appropriate to the several legumes is but sparingly present, or totally absent, in these mineral-deficient soils. On the evidence placed before us, there would seem to be little doubt that the careful balancing of manurial ingredients will have to play a more than usually important rôle in the improvement of South African grasslands, but the economic prospects will be greatly enhanced if by proper manuring it is thus rendered possible to introduce better species of plants, and especially if these can be made to include legumes, the successful introduction of which would not only add to the nitrogen-calcium content of the ration offering to the grazing animal, but also react economically on the nitrogen-phosphate balance that the scheme of manuring adopted should aim to maintain.

With regard to the grasses, no preconceived reservation should be made as to what species might prove valuable: thus for certain difficult situations in New South Wales such an unlikely grass as tor grass (*Brachypodium pinnatum*), which is nothing but an objectionable weed in Britain, has been shown to be of possible value and worthy of more serious trial; while on soils as deficient in minerals as those of South Africa, creeping soft-grass (*Holcus mollis*), perhaps the least desirable of grasses in British pastures, might prove to have a certain, though probably very limited, application.

The extreme poverty of South African soils in organic matter must tend to create an unsatisfactory soil condition from the bacteriological point of view, and this leads Sir Frederick to the opinion that the chief chemical rôle of organic matter is perhaps to supply carbon for the soil bacteria, and that a substance rich in organic carbon should contribute to complete fertilisers. To make good, so far as possible, the humus deficiency of these soils is obviously of the first importance, not only to maintain soil fertility, but also, perhaps almost equally, as a means of ameliorating the influence of drought, and consequently the farmer needs to adopt a system of management which will so far as possible augment the plant residues returned to, or retained in, the soil.

Thus in this connexion the time of application of nitrogenous fertilisers in support of phosphatic manures is perhaps as important as its presumable effect on the plant's ability both to collect and utilise water to the best advantage, since the root system (the development of which is favoured by phosphatic manures) of an arable crop must bear a close relation to humus formation in the soil. Consequently, investigations designed to establish 'the most water-economising' scheme of manuring applicable to different crops should go beyond merely an exploration of the factors which influence the economic use of water by the plant in the production of dry matter of the part or parts of the plant constituting a particular crop.

The insistence on the significance of humus deficiency adds emphasis, we think, to the importance of a crop like lucerne in the economy of South African husbandry, and the more so if, as Sir Frederick considers probable, the nitrogen-fixing organism associated with the wattle (another leguminous plant) is also capable of bringing the phosphates of the soil into organic combination. The growing of lucerne does not, however, represent the only cultural means of increasing the humus content of arable soils; the same end could be achieved by maintaining leys consisting of other plants, or by encouraging, in the first instance by the purposeful sowing of seeds and the generous application of manures, a volunteer flora of annual grasses and clovers such as undoubtedly contributes to the fertility of the Australian wheat belts.

On the balance, there would seem to be evidence to suggest that the evolution of high farming in Australia and in South Africa presents something in the nature of an antithetical parallel. In Australia, it was when the husbanding of water by improved fallow methods became well understood that the need of artificial manures (still chiefly phosphates) was fully appreciated and the potential usefulness of the alien annual flora realised; in South Africa, perhaps it will be when the deficiencies in plant foods have been artificially rectified that an impetus will be given to further endeavour in the direction of conserving moisture, and to the introduction of valuable sward-forming and humus-creating plants.

The problems of the two countries are in many respects very similar, and Sir Frederick's final suggestions, though made to the geneticists of South Africa, are equally applicable to those of Australia, as indeed they are in their broad implications to the whole body of economic plant breeders. In laying emphasis on the desirability of discovering races of maize with male inflorescences which will continue to produce pollen over a long period, he in fact directs attention to the need of the fertilisation affinities of our cultivated races of plants being in accord with the restrictions imposed by the conditions under which we expect them to grow. It is probable that the chances of successfully inducing the spread of a plant like white clover through some of the grasslands of South Africa would be increased in proportion as early and abundant seeding races could be selected for introduction, while it is equally probable that the most successful pioneer plants in regions of low rainfall are self-fertile annuals with the maximum ability for setting and ripening seed quickly. The plant breeder who seeks to take up Sir Frederick's challenge and to breed varieties of crops designed to utilise manures to the most economic advantage may take heart from the fact that it is undoubtedly true that different strains of grasses of one and the same species, at all events, react to fertilisers, both qualitatively and quantitatively, in an appreciably different manner.

Future of Australian Aborigines.

FOR some time past certain sections of the public in Australia have been much exercised by the present conditions and the future of the aborigines. The question was brought into special prominence some five or six years ago by Dr. Basedow, the anthropologist, on his return from one of his expeditions to Central Australia. As a result of his observation of conditions among the aborigines on that occasion, he organised a number of public meetings in Adelaide and elsewhere and aroused a public feeling sufficiently strong to secure the setting aside by the South Australian and Western Australian Governments of a reservation for the aborigines of 62,000 square miles lying across the boundary of the two territories.

There is, however, reason to believe that the hopes for the amelioration in the condition of the aborigines then entertained by the promoters of the movement have not been fulfilled, and it has been stated categorically by Prof. Wood Jones, in an address to the Australian Association for the Advancement of Science, that the provision forbidding the granting of concessions for the exploitation of minerals within the reserved area has been deliberately ignored by one of the governments concerned. At present the aborigines come under the respective State governments, each of which has its own Protector of the Aborigines, with

a subordinate staff; but there has been a strong expression of opinion that the care of the aborigines should be under the Commonwealth Government.

Recently the Commonwealth Government has had under consideration certain recommendations made by Mr. J. W. Bleakley, Chief Protector of the Aborigines for the State of Queensland, dealing with the aborigines and half-castes of North Australia and Central Australia. Mr. Arthur Blakeley, Minister for Home Affairs, has now made known the decision of the Commonwealth Government on the proposals, after taking into account recommendations which had been put forward by the Melbourne Conference of Missionary Societies and other bodies interested in the aborigines, as well as the administrations of North Australia and Central Australia and the Department of Home Affairs.

Certain recommendations as to wages are to be adopted, though not that which urges the payment of wages in goods instead of money—a point upon which a strong opinion has been expressed at one time and another in view of wasteful expenditure of the money wage. Accommodation for workers is to be improved under the supervision of the Protectors; and though the co-operation of employers is to be invited in securing an improved moral atmosphere, no extension of the existing law against soliciting and procuring is proposed, nor are employers to be required to employ only the married. The administration of the existing law, however, is to be tightened up. A recommendation for an aboriginal hospital contiguous to the general hospital is set aside, on financial grounds, for later consideration. It is not considered necessary that the existing reservations lying contiguously in the three States of Central, South, and Western Australia should be extended, as they are only sparsely populated by aborigines at present; but the Commonwealth Government is in communication with the State governments in connexion with the suggestion that the whole of the area in the three reserves should be placed under Commonwealth control. The most important decision, however, is that the whole of Arnheim Land is set aside as a reservation for aboriginals.

The decisions of the Commonwealth Government, excepting for the creation of a reserve in Arnheim Land, may seem relatively unimportant. Actually they mark an advance in dealing with the aboriginal question upon which all who are concerned with the interests of the aborigines may well feel cause for congratulation. In a recently published book, "The Australian Aboriginal as a Human Being", by Mr. M. M. Bennett, the case for the aboriginal is temperately set out. In that book, those who will may read the grave indictment of the treatment of the black fellow by the white—all the more serious because the greater part of the evidence is drawn from official documents.

There can be little doubt that, unless measures are taken without delay, in a few years the aboriginal will become extinct. On humanitarian grounds this is, to use a mild term, discreditable; on scientific grounds it is to be deplored. From the scientific point of view, the disappearance of the aboriginal, even as he exists to-day, would be a calamity. Spencer and Gillen saved from oblivion a vast amount of material which demonstrated the value of the Australian evidence in its bearing upon the early history of society and culture. Even now much further study is needed, for which the data still exist, especially among the remoter and less known tribes. A few years more and it will be too late; the evidence will have vanished for ever.

Scientific Bibliography.

Commonwealth of Australia: Council for Scientific and Industrial Research. Catalogue of the Scientific and Technical Periodicals in the Libraries of Australia. Edited by Ernest R. Pitt. Pp. xxiv + 1208. (Melbourne: H. J. Green, 1930.) 10*s*.

THE problem of rendering available to scientific workers the torrent of information now being poured out by the Press is in urgent need of thorough investigation. Obviously, the task comprises five processes—(1) it is necessary to ascertain exactly and immediately all that is published, so that no information may be overlooked; (2) means must be provided for collecting all the material, in order that it may (3) be thoroughly indexed, so that (4) complete bibliographies on special subjects may be supplied to research workers on demand and (5) they may be able to obtain the volumes containing the desired information for study. Merely to state these requirements is to realise that not a single one of them is adequately met. Yet the cost of an organisation to deal completely with the task would not be much greater than that of the upkeep of one of the large public libraries, certainly much less than of some in America, and, until a practical solution to the problem, as a whole, has been found, scientific workers must continue to waste their energy in useless repetition. It is time that the question was taken in hand.

Although, however, librarians generally appear scarcely to have realised the existence of the problem, they are at least beginning to appreciate the need for attempting to make lists of published literature, hence what may be called the union catalogue movement.

Union catalogues are confined mainly to periodical literature. The earliest known example of such a catalogue appears to have been one of 14 pages published in Milan in 1864. The German "Gesamtverzeichnis der ausländischen Zeitschriften" issued in 1914 to 1924 contains about 14,000 periodicals filed in about 1400 libraries. A French union catalogue "Inventaire des périodiques des bibliothèques de Paris" was issued by the Academy of Sciences in 1924–25. This catalogue represents 115 libraries and contains 16,000 periodicals. The Swiss catalogue is entitled "Verzeichnis ausländischer Zeitschriften"; the third edition, published in 1925, contains nearly 9000 periodicals from 387 libraries. A Norwegian union catalogue, "Utenlandske Tidskrifter", appeared in the same year, containing 4200 periodicals from 96 libraries. The British catalogue known as the World List of Scientific Periodicals was completed in 1927. It is a list of upwards of 24,000 periodicals contained in about 150 libraries. The union list in America is even larger, containing about 75,000 periodicals representing 225 libraries, but includes other than scientific periodicals. A new edition of the "List of Serial Publications in the Union of South Africa" was completed in 1927 and contained about 3000 periodicals from 44 libraries.

The figures quoted serve to show the inadequacy of the provision for scientific reference in different countries. Great Britain is fortunate in having one of the largest collections of scientific periodicals. But many of these are not available for loan to any research worker who may require them, and numbers of periodicals are not represented at all.

The present work contains about 10,000 periodicals filed in 132 libraries in the Commonwealth of Australia, is clearly printed, and shows evidence of very careful compilation. The editor is to be congratulated particularly on having resisted the popular clamour for a catalogue prepared without rules, "as reason panders will". The preface states: "The main object of the catalogue is to enable the research worker to ascertain readily where a reference met with in the course of his studies may be consulted. A subsidiary, but nevertheless important, purpose is to serve as a guide for Australian librarians to the latest methods of cataloguing periodicals." It would be an enormous simplification of the task of listing scientific literature if all catalogues could be prepared on a uniform system, so that entries prepared in different libraries could be brought together readily into one alphabet. As has already been pointed out for indexing information, so in cataloguing also, there is need for the adoption of a standard system. It is encouraging to see that in Australia this need is recognised.

Unfortunately, this cannot be said of some of the countries in which larger union catalogues have been prepared. The public may be excused for asking that periodicals should be entered where they may expect to find them. The librarian knows that the first essential of a good catalogue is a rigid system of rules, which shall provide one place, and one place only, for a given publication. Nevertheless, some members of the profession appear still to be in sympathy with Mr. J. G. Cochrane, who, when asked before the Royal Commission on the Management of the British Museum, in 1850, "Do you object to rules in any compilation of catalogues?" said, "Yes, very much". Thus a number of important union catalogues of periodicals attempt merely to list periodicals under their titles, with the result that entries are collected in masses under general headings such as 'Bulletin', 'Journal' and 'Report', and, owing to the great variety of small changes possible in the titles, it becomes exceedingly difficult to find the periodicals at all.

In the present work Mr. Pitt has eliminated a great deal of confusion by recognising that publications are characterised more particularly by the name of the issuing body than by their titles, and has entered them accordingly. Still further difficulties would have been avoided if the British Museum rule had been followed exactly.

S. C. BRADFORD.

Landscape for the People.

National Parks: and the Heritage of Scenery. By Dr. Vaughan Cornish. Pp. xi + 139. (London: Sifton Praed and Co., Ltd., 1930.) 5s. net.

THE appointment by the Prime Minister of a Departmental Committee to inquire as to the desirability and the feasibility of establishing one or more national parks in Britain has stimulated interest in the claims of different areas to be regarded amongst the elect. Often the claims are backed by local sentiment and little more, small

attention being given to the minimum requirements which any national park must possess if it is to meet the needs of the people. The ideal park must be spacious; it must be varied in aspect, representing many types of unspoiled Nature, mountain and valley, moorland and forest, stream and lake; its fauna and flora also must be varied and rich; it must be peaceful, accessible, and yet remote from the bustle of traffic; and, if the project is to make headway in the near future, it must be land the value of which is not exorbitant.

Dr. Vaughan Cornish examines with the eye of the practised geographer the areas in Britain which he regards as suitable for national parks. They are not very many: in Scotland, the wild regions of Glen Affric, the Cairngorms, and the Cuillin Hills of Skye; in Wales, Snowdonia; and in England a variety of aspects, from the moorlands of Tynedale, adjacent to the Roman Wall, and the wilder scenery of Lakeland, to areas of special and restricted character, such as the Norfolk Broads, Dartmoor, the South Downs, the New Forest and the Forest of Dean, and the sea-cliffs of Pembroke and North Cornwall.

In enumerating the characteristics and merits of each of these regions, Dr. Cornish restricts consideration to the scenic aspects, on the ground that he is dealing with "sanctuaries of scenery for the preservation of the sense of communion with Nature on the part of our people". It is an unfortunate restriction, for it ignores the fact that to many the sense of communion with Nature is bound up with observation of the plants and animals of the country; natural history and natural scenery march side by side. How can one assess the value of the Cairngorms as a national park, without discussing the interests of the unique primeval pine-woods of Rothiemurchus and Glen More (simply mentioned as 'forests'), or the outstanding members of its fauna, red deer and roe and Arctic hares, its golden eagles, ptarmigan, dotterel, greenshanks, and snow-buntings? It was for good reason that the terms of reference of the National Parks Committee included "fauna and flora", and the omission of this aspect of the question limits the value of the analysis presented in this volume.

We know that specialists in botany and natural history have declared that preservation of fauna and flora is incompatible with the full play of a national park, and the author concedes this point. But from our knowledge of the expert egg-collecting which now takes place, without let or hindrance, in that area, we are convinced that the rare birds would be safer under the watchful eyes of the park wardens; so also would it be with the wild beasts. As for the people, they themselves, recognising their heritage and the danger it would run from selfish molestation, will become the best protectors of flowers and animals.

A strong plea is made for the preservation from the spread of the seaside bungalow, so encouraged by modern ease of transport, of goodly strips of sea-cliff. That is a southern problem, for Scotland will always have its cliffs and islands, haunts of innumerable sea birds, which need no protection other than their remoteness, and the areas suggested in Pembroke and Cornwall have the great advantage that their climate favours winter as well as summer visitors.

The second part of the volume analyses the qualities and combinations of natural and artificial features which make for pictorial grouping in agricultural and urban landscape, at home and in various parts of the world. It shows the dangers of hasty and unconsidered building, and ought to suggest to local authorities and architects ways in which the needs of civilisation may be served without grievously interfering with Nature's majesty and beauty. J. R.

The Historical Approach to Science.

Pour l'histoire de la science Hellène. Par Paul Tannery. *De Thalès à Empédocles.* Deuxième édition, par Prof. A. Diès. Pp. xxiv + 435. (Paris: Gauthier-Villars et Cie, 1930.) 80 francs.

THE new second edition of this standard book is to be warmly welcomed for several reasons. It first appeared in 1887, and has been long out-of-print. It is now reissued with some additional matter (a letter and essay on Melissus by Tannery and some notes by the editor, M. A. Diès). Above all, it has an admirable preface by M. Federico Enriques, putting the case for the study of the history of science and giving an estimate of Tannery's work as a whole. Hence it will be understood that this is a book to be possessed by all who make the history of thought the main line of their study of the past, but it should be accompanied by Tannery's two other books, "La Géométrie grecque" (1887) and "Pour l'histoire de l'astronomie ancienne" (1893).

There can be no question of the unique importance of the evolution of thought which these three works cover; it is nothing less than the establishment of the framework of science in which the human mind has worked ever since, which it has

continually elaborated and is elaborating to this hour. It is therefore of perennial interest, for mankind will always be thinking it over and refashioning it in the light of new discoveries and fresh points of view. As it stands at present, there are still abundant lacunæ, frequent issues on which doubt remains and on which more than one opinion may be legitimately held. On the other hand, certain conclusions now stand out above all question. It may be interesting to set down a few of these as they appear from this latest edition of Paul Tannery's book.

In the first place, we know for certain that Greek science arose from the intercourse of Greek minds with Egyptian and Babylonian, especially the former. It can first be dated in the sixth century B.C., and was always connected in Greek tradition with the name of Thales of Miletus, the leading name among the seven Sages. What we do not know is how much to attribute to Thales personally and how much to the Egyptians, how far the Egyptians had gone in geometry, arithmetic, or astronomy, or whether these sciences are due, as sciences, entirely to Thales and his successors. On these questions Tannery is pro-Greek, but not pro-Thales. Thales himself he treats as a somewhat mythical figure, but has no doubt that it was Greeks of about that time who built up the first geometrical and rational cosmological conception of the world. There is probably much more to be discovered about the early thought and achievement of the Egyptians, and those who have seen the marvellous architecture lately uncovered by Mr. Firth at the foot of the Step-Pyramid at Saqqara, and attributed to the fourth millennium B.C., will hold their judgment as to the presence or absence of any particular geometrical conception in the minds of Egyptians of that age. It is hard to believe that the men who erected these things, or the Great Pyramids, had no notion of angular measurement—much easier to think that the Rhind papyrus, on which so much has been based, is a careless or ill-informed production of inferior minds.

In the volume before us, Tannery was discussing the exact import and affiliation of the cosmological ideas of the pre-Socratics—Nous, the infinite, the elements, etc. Here, it must be confessed, the importance of the speculation is much less evident than in the thinking which led to the foundation of mathematics. There is no doubt as to the affiliation of modern mathematics to that of the Greeks; Descartes goes back to Pappus, and Copernicus improves on the Ptolemaic system. But can one say the same of modern physics and chemistry? Are the atoms of Dalton in the direct descent from Anaximenes or Democritus? These physical speculations of the early Ionians often strike one as the clear but quite crude ideas of children, and, by themselves, would not justify the high esteem of the Greeks as scientific founders. This is why the three aspects of Tannery's studies —the geometrical and astronomical as well as the cosmological—should go together.

M. Federico Enriques' preface is the best defence of the study of the history of science, within that compass, that we have ever seen. It should be printed as a pamphlet and broadcast. He sees in the historical approach to science the best, perhaps the only, means of preventing science becoming a mass of detached specialisms with less and less of a spirit of synthesis or any obvious place in the general history of social progress. In the study of history man preserves his continuity with the past and consciously builds up the future; it is his special prerogative. As science, that is, orderly thinking, is more clearly recognised as the central thread in this process, it must take a corresponding place in the record which each age makes afresh for itself of its own past.

F. S. MARVIN.

Our Bookshelf.

(1) *Elementary Inorganic Chemistry.* By Dr. J. W. Mellor. Pp. x + 229. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1930.) 3*s*. 6*d*.

(2) *Intermediate Inorganic Chemistry.* By Dr. J. W. Mellor. (New edition of "Introduction to Modern Inorganic Chemistry".) Pp. xx + 690. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1930.) 7*s*. 6*d*.

DR. MELLOR has divided his well-known "Introduction to Modern Inorganic Chemistry" into two separate volumes in order to meet more adequately the needs of schools. The more elementary volume is written about the properties of air, water, and the common non-metals, with a simple discussion of some of the fundamental principles of chemistry, together with biographical notes of some of the founders of the science. Most of the text has been incorporated into the "Intermediate Inorganic Chemistry", which includes also some chapters on organic compounds and on the common metals. Both volumes are admirably illustrated and the subject matter is presented in an attractive fashion. The "Intermediate" volume contains questions at the end of each chapter, and here and there one comes unexpectedly across delightful quotations from such works as "Alice in Wonderland" and Shelley's poems. It also contains a fair amount of physical chemistry.

In the chapter on energy and matter a series of illustrations of the kinetic theory is given with the

view of enabling the imagination to grasp some idea of the "scale of magnitudes in the world of molecules". This is followed by a discussion of the bearing upon the theory of the study of ultra-microscopic particles. No mention is made of electrons, nor are the modern views of atomic structure dealt with. This is rather surprising, since an elementary discussion of the subject would probably make a stronger appeal to the young student's imagination than Planck's conception of energy quanta and Einstein's extension of his ideas, which are introduced into the section on specific heats. The chapter on classification is perhaps the weakest part of the book. It opens with a highly condensed scheme of qualitative analysis which seems to serve no useful purpose. Both the scheme and the doggerel verses which precede it might well be banished from the modern text-book. Classification of the elements is discussed up to the work of Mendeleéff, with the addition of elements discovered since then. No explanation is given of the atomic numbers which are to be found in the table on p. 289.

Telegraphy and Telephony, including Wireless: an Introductory Textbook to the Science and Art of the Electrical Communication of Intelligence. By Dr. E. Mallett. Pp. ix + 413. (London: Chapman and Hall, Ltd., 1929.) 21*s.* net.

ELECTRIC communication whether by wires or by radio is now an art of great commercial importance. It is not surprising, therefore, that there are many text-books written on the subject. Many of these deal with highly specialised applications and several are written for the telegraphist or the telephone linesman, but there are very few which attempt to give an outline exposition of the scientific principles on which the whole art is based.

In the book under notice, Dr. Mallett successfully gives such an exposition. It is designed to meet the needs of the university or technical college student who has studied electricity and magnetism up to the second year standard. It should prove useful for students preparing for the final examinations in telegraphy and telephony for the B.Sc. (Eng.) of the University of London. From the student's point of view it would have been desirable to include a few examination questions with complete solutions in various parts of the book. The explanation of the so-called skin effect is perhaps too brief, and in several places not sufficient stress is laid on the fact that sine assumptions have been made. We can commend this book to the student who intends to take up electric communication as a career.

Human Biology and Racial Welfare. Edited by Prof. Edmund V. Cowdry. Pp. xviii + 612. (London: H. K. Lewis and Co., Ltd., 1930.) 28*s.* net.

THIS book is addressed to the student about to specialise and to the general reader. It consists of twenty-five essays by eminent authorities in their own fields, and is divided into five parts leading from the origin of man to a consideration of his destiny. The contributions maintain a high scientific level and nevertheless are so written as to be easily understood by those not acquainted with technical terms. This is a somewhat remarkable achievement. But it may be asked whether the editor has not set himself an impossible task. Though care has been exercised in arrangement, the effect cannot be other than to give the impression of a collection of scraps. The field is vast and those parts of it which are touched upon are briefly, sometimes very briefly, treated. There seems to be no reason why some problems are included and others omitted. The reader finds himself setting off on a number of journeys, and before he has got accustomed to the scenery he is off again in a new direction. Integration, which is presumably one of the objects of the book, is not achieved. Those to whom the book is addressed require a guiding thread, which perhaps could be given if the book was the work of one hand; but no one with a reputation to lose would attempt the task single-handed. A worthy attempt has been made to fill a gap which undoubtedly exists by the alternative method, but with a degree of success that is necessarily limited by the defects of that method.

Fütterung der Haustiere: ihre theoretischen Grundlagen und ihre wirtschaftliche Durchführung. Von Prof. Nils Hansson. Deutsch von Dr. Franz von Meissner. Zweite, umgearbeitete und erweiterte Auflage. Pp. xv + 274. (Dresden und Leipzig: Theodor Steinkopff, 1929.) 10 gold marks.

THE first edition of this work appeared in 1926. In the present edition, Prof. Hansson has reviewed the subject matter of the former edition in the light of the progress which has been made in animal nutrition research during the last decade. A chapter on vitamins, their distribution and significance, has been inserted. The question of the biological value of the constituents of feeding stuffs is also dealt with. Other new features of the present edition include: accounts of feeding stuffs which have been introduced recently into feeding practice; the scientific aspects of poultry nutrition; the regulation of bulk in the feeding of farm animals; the mineral requirements of different classes of farm stock. The tabular matter in the final section has been augmented by the inclusion of data showing the reactions of the ash constituent of the common feeding stuffs.

The Material Culture and Social Institutions of the Simpler Peoples: an Essay in Correlation. By L. T. Hobhouse, G. C. Wheeler, and M. Ginsberg. (The London School of Economics and Political Science: Series of Studies in Economics and Political Science, No. 3 of the Monographs on Sociology.) Pp. v + 299. (London: Chapman and Hall, Ltd., 1930.) 10*s.* 6*d.* net.

THIS is a photographic reproduction of a book first published in 1916, though there is no intimation to that effect and the title-page bears the date 1930. It was, and still is, a monograph of great value for the study of primitive peoples, but so much work has been done since it was compiled that it requires considerable additions and some revision.

Letters to the Editor.

Fine Structure of α-Rays.

IT is usually assumed that the long range α-particles observed in C'-products of radioactive series correspond to different quantum levels of the α-particle in the nucleus. If after the preceding β-disintegration the nucleus is left in an excited state with the α-particle in one of the levels of higher energy, one of the two following processes can take place: either the α-particle will cross the potential barrier surrounding the nucleus and will fly away with the total energy of the excited level (long range α-particle), or it will fall down to the lowest level, emitting the rest of its energy in the form of electromagnetic radiation (γ-rays), and will later fly away as an ordinary α-particle of the element in question. Thus there must exist a correspondence between the different long range α-particles and the γ-rays of the preceding radioactive body. If p is the relative number of nuclei in the excited state, λ the corresponding decay constant, and θ the probability of transition of the nucleus from the excited state to one of the states of lower energy with emission of energy (in form of quanta or an electron from the electronic shells of the atom), the relative number of long range α-particles must be $N = p\frac{\lambda}{\theta}$. Knowing the number of α-particles in each long range group and calculating, from the wave mechanical theory of radioactive disintegration, the corresponding values of λ, we can estimate for each group the value θ/p, giving a lower limit for the probability of γ-emission. For example, for thorium-C' possessing besides the ordinary α-particles also two groups of long range α-particles, we have for transition probabilities from two excited states to the normal state $\theta_1 < 0{\cdot}4 \times 10^{12}$ sec.$^{-1}$ and $\theta_2 < 2 \times 10^{12}$ sec.$^{-1}$, which is the right order of magnitude for the emission of light quanta of these energies. With decreasing energy λ decreases much more rapidly (exponentially) than θ, so that the number of long range α-particles from the lower excited levels will be very small. (From this point of view we can also easily understand why the long range α-particles were observed only for C'-products for which the energy of normal α-particles is already much greater than for any other known radioactive element.)

A difficulty arises with the recent experiments of Rosenblum (*C.R.*, p. 1549; 1929; p. 1124; 1930), who found that the α-rays of thorium-C consist of five different groups lying very close together. The energy differences and intensities of the different groups relative to the strongest one (α_0) are, according to Rosenblum:

$$
\begin{array}{ll}
E\alpha_1 - E\alpha_0 = +\ 40{\cdot}6 \text{ kv.} & I\alpha_1 = 0{\cdot}3 \\
E\alpha_2 - E\alpha_0 = -287 & \\
E\alpha_3 - E\alpha_0 = -442 & \\
E\alpha_4 - E\alpha_0 = -421 & I\alpha_4 = 0{\cdot}005
\end{array}
$$

If we suppose that these groups are due to α-particles escaping from different excited quantum levels in the nucleus, we meet with very serious difficulties. The decay constant λ for the energy of thorium-C fine structure particles is very small ($\lambda \sim 10^{-3}$ sec.$^{-1}$), and in order to explain the relatively great number of particles in different groups we must assume also very small transition probabilities. We must assume that thorium-C nucleus can stay in an excited state without emission of energy for a period of half an hour!

We can, however, obtain the explanation of these groups by assuming that we have here a process quite different from the emission of long range α-particles. Suppose that two (or more) α-particles stay on the normal level of the thorium-C nucleus. It can happen that after one of the α-particles has escaped the nucleus will remain in an excited state with the other particle on a certain level of higher energy. (In this case the energy of the escaping α-particle will be smaller than the normal level and obviously will not correspond to any quantum level inside the nucleus.) From the excited state the nucleus (thorium-C'' now) can afterwards jump down

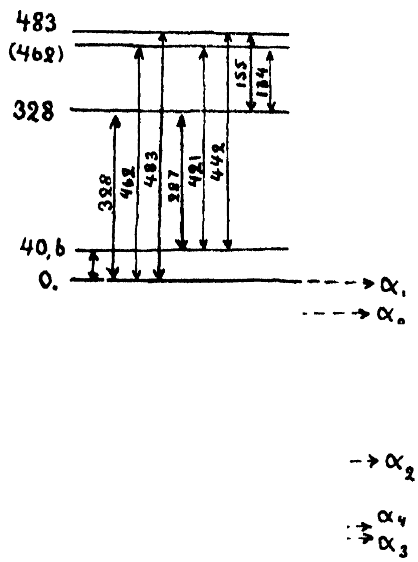

FIG. 1.

to the normal level, emitting the energy difference in form of a γ-quantum.

Thus the relative number of different groups will not depend on the probability of γ-emission but only on the transition integral:

$$W = \iint f(r_{1,2})\psi_{E_0}(a_1)\psi_{E_0}(a_2)\bar{\psi}_{E_n}(a_1)\bar{\psi}_{E\alpha_n}(a_2)\,dv_1 dv_2$$

where $f(r)$ is the interaction energy of two α-particles at a distance r apart, ψ_{E_0} and ψ_{E_n} the eigenfunctions of an α-particle in the normal and n^{th} excited states, and $\psi_{E\alpha}$ the eigenfunction of an escaping α-particle with the energy: $E\alpha_n = E_0 - (E_n - E_0)$.

According to this scheme, the γ-rays corresponding to different fine structure groups of thorium-C must be observed as γ-rays of thorium-C (ejecting electrons from K, L, M, . . . shells of the thorium-C''-atom) and not as the rays of thorium-B, as we would expect in the case of long range particle explanation. The level scheme of the thorium-C''-nucleus as given by fine structure energies is represented in Fig. 1.

In the observed γ-ray spectra of thorium-$C + C''$ (Black, *Proc. Roy. Soc.*, pp. 109-166; 1925) we can find lines with the energies: 40·8; 163·3; 279·4; 345·8; 439·0; 478·8; 144·6 kv. fitting nicely with the energy differences in Fig. 1.

Thus we see that the fine structure group of highest energy corresponds to the normal level of the nucleus, while the other groups are due to the ordinary α-particles which have lost part of their energy, leaving the nucleus in an excited state.

I am glad to express my thanks to Dr. R. Peierls and Dr. L. Rosenfeld for the opportunity to work here.

G. GAMOW.

Piz da Daint,
Switzerland, July 25.

Vitamin Content of Marine Plankton.

THE synthesis of vitamin A in *Nitzschia* and other organisms grown in cultures of artificial sea-water (Jameson, Drummond, and Coward, *Biochem. J.*, **16**; 1922, and subsequent workers) has constituted the main evidence for assuming that marine organisms rely upon phytoplankton for their supplies of vitamins. A search for vitamin D in the same diatom (Leigh-Clare, *Biochem. J.*, **21**; 1927) proved unsuccessful; and little further attention has been given either to the possible presence and rôle of vitamins A and D in planktonic organisms or to the origin of the exceptionally rich stores found in the cod's liver.

To determine what may be, in the natural habitat of the plankton, the possible source and supply of vitamins A and D, plankton was collected and extracted by one of us (E. R. G.). Collections of diatoms and of zooplankton were made from Port Erin in the spring and summer of 1928, and through the kindness of Sir F. G. Hopkins the work of extraction was carried out at the Biochemical Laboratory, Cambridge. The dried plankton was treated in soxhlets with light petroleum and precautions were taken to ensure against overheating and against oxidation through access of air.

Vitamin tests have been conducted both at the Department of Biochemistry, University College, London, and, through the courtesy of The British Drug Houses, Ltd., by Dr. S. W. F. Underhill in their Physiological Laboratory. The feeding tests for vitamin A were supplemented by observations upon the colour reaction with antimony trichloride and by spectroscopic examination. In testing for vitamin D the degree of healing was determined both by histological (line test) and by X-ray examinations.

The following is a summary of the results hitherto obtained:

Nature of Test.	Result from Phytoplankton.	Result from Zooplankton.
VITAMIN A.		
(1) Growth tests .	Positive (in 20 mgm. doses)	Negative
(2) Antimony trichloride	Strong blue colour obtained	Negative
(3) Absorption spectrum	..	No band at 310–330 $\mu\mu$
VITAMIN D.		
(1) Line test . .	Doubtfully positive (much less than 100 Coward antirachitic units per c.c. in 0·02 c.c. doses)	Positive (less than 100 Coward antirachitic units per c.c. in 0·02 c.c. doses)
(2) X-ray . . .	Negative (in 50 mgm. doses)	Negative (in 20 mgm. doses)

The extracts of both animal- and phyto-plankton were strongly pigmented and with antimony trichloride produced red and yellow colours which in some samples were so intense as to render the determination of the blue colour almost impossible. When the antimony trichloride reaction was applied to the unsaponifiable fractions prepared from some of the oils the response was much more definite. A clear blue colour was given by the material isolated from the phytoplankton oil. How far this was due to carotene was not determined by spectroscopic examination, as the quantity of material available was insufficient, but that pigment was undoubtedly present. The unsaponifiable fraction examined from two zooplankton oils did not give a blue coloration with the antimony trichloride.

The probable absence of vitamin D in the phytoplankton is in agreement with the result obtained by Leigh-Clare for *Nitzschia*, which showed no antirachitic activity. It has not been possible to test the amount that would be required to show an order of activity much lower than 100 units per c.c.; therefore the possibility of its having a strength comparable to that of butter (2 units per c.c.) remains an open question. Small doses of the animal plankton, on the other hand, seemed to show fairly definite signs of antirachitic activity, and the possible discrepancy arising in the X-ray examination may be due to the greater delicacy of the line test. The tests suggest that the small amount of vitamin D which appears to be present in these animals results from their irradiation while in surface waters, rather than from a prolonged diet of phytoplankton.

E. R. GUNTHER.

London.

Scattering of X-Rays by Bound Electrons.

IN two letters to NATURE (May 17 and June 7), Dr. B. B. Ray announces an interesting experimental observation on what he calls "Scattering of X-rays by Bound Electrons". He allowed $K\alpha$ radiation of copper to pass through soot and air, and found that the photograph of the transmitted beam showed, besides the primary $K\alpha$ beam, lines of lesser frequency, namely, $\nu - \nu'$, where ν is the characteristic K-frequency of carbon, oxygen, and nitrogen (matter traversed). The nickel $K\alpha$ radiation also shows a similar modification, the quantum being deprived of a part of its energy corresponding to the K-radiation of the substance traversed.

The object of the present note is to point out that the phenomenon observed has nothing to do with scattering as Dr. Ray seems to think, but is a case of photoelectric ionisation. When a beam of frequency ν traverses matter, it may hit an electron in the K-shell, and will thereby be deprived of a part of its energy equal to $h\nu_K$ where ν_K is frequency of the characteristic K-radiation of the substance traversed. The modified beam will have, according to energy principles, the energy $h(\nu - \nu_K)$, and this may pass on as such, or be absorbed by the electron, which will be ejected with an equivalent velocity. This method has been utilised by De Broglie and Robinson in determining the energy levels of different atoms (from an analysis of the photoelectrons emitted), and by Ellis, L. Meitner, and others in determining the wave-length of nuclear γ-rays. This last application is very interesting, because as the γ-rays from the nucleus of a radioactive substance, say radium-actinium, pass through the nucleus, they release β-rays having the energies $h(\nu - \nu_K)$, $h(\nu - \nu_L)$, etc., and when the β-ray spectrum is analysed, it reveals the characteristic difference $(\nu_{K_1} - \nu_{L_{11}})$, etc., of the atom traversed.

Dr. Ray has, however, gone a step further, and has been the first to analyse the modified (by absorption) beam of primary quanta by a spectroscopic method, and supplemented the work of De Broglie and Black. It is therefore a remarkable experimental verification of photo-ionisation, and hence it easily explains why no modified beam is observed in any other than the forward direction.

The diffuseness of the modified lines is due to the fact that the characteristic $K\alpha$ radiation of the light elements from neon downwards is very diffuse, as observed by Söderman (*Zeit. f. Physik*, **52**), and the diffuseness increases the lighter the element. It appears to me that it affords probably a far more accurate and less troublesome method for determining wave-lengths of the softer radiation from light

elements, and also of such radiation as originates from the outer levels of compound and other aggregate formations. SALIGRAM BHARGAVA.

Physics Department,
University of Allahabad,
July 10.

IN continuation of my previous notes in NATURE (May 17 and June 7, 1930), I have further observed the following lines :

Incident Radiation.	Scattering Substance.	Modified Lines.	Origin.
Ni$K\beta_1$	C	1552 X.U. (587·0)	Ni$K\beta_1$ – C$K\alpha$
ν/R = 608·7	N	1573 X.U. (579·0)	Ni$K\beta_1$ - N$K\alpha$
	O	1602 X.U. (569·0)	Ni$K\beta_1$ O$K\alpha$
Fe$K\beta_1$	C	1825 X.U. (499·0)	Fe$K\beta_1$ - C$K\alpha$
ν/R = 519·9	N	1859 X.U. (490·0)	Fe$K\beta_1$ - N$K\alpha$

The figures in the bracket denote the values of ν/R.

The values of the $K\alpha$ radiations (in ν/R) of carbon, nitrogen, and oxygen are 20·4, 28·7, and 38·3 respectively (Söderman, *Zeit. f. Phys.*, **52**). These modified lines are broad, diffuse, and weak, and as such they were only measured by a glass scale. The error in the measurement may be so great as 4 X.U.

Though Coster, Ehrenberg, and Kast (as mentioned in my previous notes), following Bergen Davis and his collaborators, who were the first to report the detection of such modified lines in the scattered rays, have failed to detect any line on the photographic plate, through the scattering of X-rays by an atom in a direction at right angles to the direction of propagation, where the Raman effect is usually observed, this experiment clearly shows that the modified lines produced by the "scattering of X-rays by bound electrons" are observed in the direction of transmission of the incident radiation. It further follows that to be consistent with the current definition of scattering and absorption, the effect observed by me, which was described in my previous notes to NATURE as "modified lines due to the scattering of X-rays by bound electrons", would be more correctly described as modification due to part-absorption of the incident radiation by atoms. Optical Investigations on the Formation of the Latent Photographic Image.

THE effect of colouring of the alkali halides, such as rock salt, with X-rays, radium radiation, or far ultra-violet radiation, is due in the light of modern knowledge to the transference of the valency electron from the chlorine to the sodium. The latter is suspected to be deposited in the lattice in the state of neutral atoms. The new absorption band, causing, for example, the yellow colour of rock salt, can be made to disappear by exposing the coloured salt to the rays it absorbs, that is, the blue-violet ones, or by heating it. A plausible theory is that in this case the backward transference of a valency electron takes place. In both cases the liberated electrons must cause the photo-conductivity effect, and this was indeed observed for the decolorising effect and studied by Pohl and Gudden and their collaborators.

On the other hand, the photo-conductivity effect was found in silver bromide and was investigated by Dr. Toy and his collaborators and also by Kirilov (*Zs. f. wiss. Photographie*, 1928); as Dr. Toy shows, it is closely correlated with the primary photographic process, and both are due to the same primary separation of the electron from the bromide ion.

This analogy between the processes taking place during the illumination of rock salt and silver bromide suggested some optical investigations on the absorption spectra of unexposed and exposed silver bromide, in the hope that they may contribute to the theory of formation of the latent photographical image. The silver bromide was used in the form of layers of fused salt or in large crystals, obtained by the Kyropoulos method. The following results were obtained :

(1) The silver bromide layers and crystals, when not illuminated, are lemon coloured; their absorption band lies in the blue-violet and the near ultra-violet region of the spectrum, and can be regarded as analogous to the far ultra-violet absorption band of sodium chloride (near 1800 A.).

(2) Illumination with rays it absorbs or with X-rays makes the layer quickly change its colour from yellow to emerald-green. The absorption band of this phase lies in the red and infra-red parts of the spectrum; it was measured by us as far as 2000 $m\mu$ and found to consist of a maximum at 610 $m\mu$ and a continuous absorption in the infra-red. It seems to be analogous to the absorption band of the yellow rock salt and can be regarded as the "absorption spectrum of the latent image" (A. Smakula, *Zs. f. Phys.*, **59**, p. 604; 1930).

(3) This view is supported by the observed disappearance of this 'latent image' on heating and by the action of red and infra-red radiations, which is analogous to the decolorising of the yellow salt (Herschel's phenomenon).

(4) Przibram and his collaborators have found that radiations of a given intensity cannot cause colouring of rock salt exceeding a certain maximum limit. The same is observed for the silver bromide layers. The increase of exposure does not completely compensate the decrease in the intensity (analogous to the Schwarzschild law).

(5) My investigations on the coloured rock salt, which are to appear shortly in the *Zeitschrift für Physik*, have led me to conclude that under some conditions (simultaneous illumination and heating) the neutral sodium atoms can aggregate into larger colloidal clumps; the absorption spectrum of such a colloidal system can be evaluated on the basis of the known theories of Maxwell-Garnett and G. Mie. The application of this evaluation to the system sodium–sodium chloride gave results which are in good agreement with the observed red, violet, and blue colour of the rock salt samples.

On the other hand, silver bromide layers, when exposed to the simultaneous action of the active and decolorising radiations, become brown or, when slightly heated, reddish brown (visual blackening); different samples may have a slightly different colour. The analogy with the change of colour of the blue rock salt by heating and other considerations leads me to assume that the brown colour is due to colloidally-distributed silver particles; the application of Mie's theory to the system silver-silver bromide seems to support this view. The Splitting of Spectral Lines at Scattering of Light by Liquids.

As was pointed out in my previous communication (see NATURE, Aug. 9, p. 201), when light is scattered by liquids or crystals, there can be observed a splitting of spectral lines which may be ascribed to the influence of elastic heat waves. In the case of strongly scattering liquids, the change of the frequency is given by the following equation:

$$\nu = \nu_0\left(1 \pm 2n\frac{v}{c}\sin\frac{\theta}{2}\right) \quad n = 0,\ 1,\ 2,\ 3,$$

where ν_0 is frequency of the incident light, v and c are velocities of sound and light in the medium, θ is the angle between the incident and scattered rays. It is interesting to note that the length of sound waves to which this splitting may be ascribed is of the same order of magnitude as the wave-length of light.

I wish to give here some details regarding this phenomenon and also to describe some new experiments.

The observed displacement of components does not strictly follow the above equation. In all cases, with the exception of aniline, the observed values are somewhat greater than the calculated ones. In these calculations, the experimental values for the velocity of sound obtained chiefly by the Kundt method were used. However, the velocities of sound calculated from the coefficient of compressibility and density of liquids also do not give values which are in full agreement with experiment.

The intensities of 'red' and 'blue' components are, as it seems, nearly equal. The intensities of inner components (that is, corresponding to $n = 1$ in the above equation) are greater than those of the outer ones (corresponding to $n = 2, 3, \ldots$), and the intensity of the undisplaced line is still greater but perhaps is not greater than twice the intensity of the nearest displaced components. The greatest relative intensity of the undisplaced line was observed in benzene and water. Perhaps the increased value of the intensity of this line is due, at least partly, to dust and contamination of the liquids, which did not in these experiments undergo a special purification (this refers particularly to water, for which the intensity of scattered light is small). It must be remembered that it is very difficult to judge the relative intensity of lines from spectrograms obtained with the echelon grating.

The width of displaced as well as of undisplaced components is not the same for different liquids. It is less in benzene, which gives the displaced lines most distinctly; on the other hand, ethyl alcohol and ethyl ether give diffuse, barely distinguishable lines. In benzene the width of components may be estimated at 0·025 A. Between all the components there is a continuous spectrum.

Some experiments on polarisation of scattered light were made with benzene. When the incident light is not polarised, the undisplaced and the two neighbouring displaced components, that is, lines corresponding to $n = 0$ and $n = 1$ in the above equation, are strongly polarised, the electric vector being perpendicular to the direction of the incident beam. On the contrary, the other components, that is, corresponding to $n = 2, 3, \ldots$, are, as it seems, almost quite unpolarised.

I wish to return to the question of the maximum possible value of n, or the maximum possible displacement of components. If the appearance of these displaced components is due to the diffraction by 'heat wave gratings' of harmonics, the value of n will be limited by the fact that in liquids as well as in solids it is possible to assume a limiting maximum frequency of Debye's 'acoustic spectrum' which corresponds to a wave-length equal to twice the mean distance between molecules. If this distance is of the order of 3–4 A., the limiting frequency will be of the order of $2\text{–}2{\cdot}5 \times 10^{12}$ sec.$^{-1}$ and will produce a displacement of about 15 A. Maybe this is the cause of the broadening of the scattered lines in both directions extending nearly to the above distance which was noticed in liquids (for example in benzene) by many observers (Cabannes et Daure, *C.R.*, **186**, p. 1533; 1928; Raman, *Ind. Jour. of Phys.*, 4, p. 399; 1928; Gerlach, *Ann. d. Phys.*, **5**, p. 301; 1929). Experiments which are now in progress seem to support this view.

The Atomic Diameters of Hydrogen and the Inert Gases with respect to Electrons of Very Low Velocity.

THE wave-mechanical treatment of the problem of the scattering of α-particles by neutral atoms has been given by Sommerfeld ("Wave-Mechanics", pp. 192-199). To simplify the calculations he assumes that all the electrons in the atom under consideration are concentrated in the K-shell and have no influence on one another. With similar assumptions, but by a somewhat different procedure, we have made an approximate calculation of the scattering of very slow *electrons* by neutral atoms. This has enabled us to calculate the atomic diameters of hydrogen, helium, neon, and argon with respect to electrons of vanishingly small velocity (0-volt electrons). We obtain the surprising result that the atomic diameters of these gases should vary *inversely* with respect to their atomic numbers. It is obvious that this result should come out most correctly by experiment in the relative magnitudes of the atomic diameters of hydrogen and helium, as only the K-shell exists in their case, and that the error introduced by the above assumptions as applied to the present problem will become much greater as we pass to the higher atomic numbers owing to the greater number of electrons far outside the K-shell.

Actual experimental values of these atomic diameters with respect to 0-volt electrons have not yet been obtained. The best available data for comparison are those obtained from experiments by Townsend and Bailey. In Fig. 10, p. 28, of Townsend's "Motion of Electrons in Gases" (Oxford) curves are given which exhibit the relationship between the mean free paths of electrons of varying velocity in hydrogen, helium, neon, and argon. The velocity of the electrons ranges from 2 volts to 1/9 volt in this diagram for the case of hydrogen and helium, but only from 2 volts to slightly below 1 volt in the case of argon and neon. At an electronic velocity of 1 volt the mean free paths are in the ratios 3 : 8 : 40 : 140 for hydrogen, helium, neon, and argon respectively, of which the atomic numbers are 1, 2, 10, 18. All the curves are divergent towards lower velocities, so that these ratios would become correspondingly larger below 1 volt.

Townsend and Bailey showed in 1921 that the mean free path in argon reaches a maximum at 0·39 volt (as has recently been verified by Ramsauer and Kollath: see NATURE, Mar. 15, 1930, p. 427), and, as there is reason for believing that a maximum occurs in the case of all gases, extrapolation of these curves towards lower velocities is impossible. Since we may take the mean free paths as inversely proportional to the atomic cross-section or the square of the atomic

diameter, the above ratios show that the wave-mechanical treatment of the problem gives the correct experimental result qualitatively for hydrogen, helium, neon, and argon; in the case of hydrogen and helium there is even fair quantitative agreement.

We wish to emphasise that our calculation can be regarded only as a first approximation, because we are dealing with slow electrons, which will be considerably influenced by the extra-nuclear electrons beyond the K-shell, whereas in the case of the scattering of α-particles the effect of the electrons outside the nucleus is only of secondary importance. The way in which this fact modifies the results above mentioned will be given in our detailed paper which will be published shortly.

Noise Associated with Lightning.

SOME years ago I directed attention in NATURE to a swishing sound that is sometimes heard when a flash of lightning is very close to the observer. I had at that time never heard the sound myself. I heard it, however, very distinctly on the night of Aug. 29–30. I had been expecting a flash to come close, as a very active storm centre had been moving directly towards this spot, with steadily decreasing intervals between the cloud to earth flashes and the thunder. I did not see the actual flash, only the illumination of the garden through the open window; it was very brilliant and was followed instantly by a noise as though a shower of large water drops had been thrown on to a hot metal plate; this was followed almost instantly by the thunder. I think there was a slight interval between the swish and the thunder, but it must have been only a fraction of a second; I had been counting seconds after previous flashes, but with this one I had not time to begin to count before the thunder came. The flash must have struck a point well within a hundred yards of my room, and I suspect that it struck the lightning conductor on the house. The noise was heard by my daughter and by two other people in the house. It was also heard by two people in a cottage about 50 yards from the house; one of them likened it to a red-hot poker being plunged into cold water, the other to the sound of the arc when two electric cables are short circuited.

The origin of the noise is obscure. I feel inclined to think that it is caused by some of the branches into which the main discharge often divides before reaching the ground; it may well happen that a number of these may be nearer to the observer than the main discharge and so be heard first. The noise is not unlike the crackle of a brush discharge on a large scale. The chief argument against this explanation is that a correspondent in NATURE described the sound as occurring not after but before the flash. But it seems possible that on some occasions brush discharges may occur just before a flash. At any rate, this sometimes occurs with a highly charged Wimshurst machine.

Another point that I noticed (not for the first time) in the recent storm was that there seemed to be definite active centres. When I first observed the storm about 9 P.M., summer time, there were two centres where most of the brightest flashes were occurring, one on a line through Chichester, the other on a line just north of Portsmouth, though both centres were probably at a good distance farther than either town; almost all the flashes at this time were connected with one or other of these centres, though many of the cloud to cloud flashes travelled long distances in the sky. The 'Portsmouth centre' moved nearer, taking a course that brought it within about five to six miles to the north-west of us. Meanwhile, another centre of activity had moved a little south of us; this produced some very good flashes a mile or two to the south-east and east, and finally moved away in the direction of London. It could be followed for a long time, the flashes appearing, owing to increasing distance, to become shorter and fainter. Finally, I noticed another centre on a line a little to the south of the direction of Portsmouth, and this centre it was that was responsible for the flash described above; it also produced three other flashes quite close by, and one of these made the peculiar noise, though I did not hear it myself, probably because I was going round the house to see if any damage had been done by the first flash and happened to be in a passage where there was not an open window.

Stoner Hill, Petersfield, Sept. 1.

Sunspots and Pressure Distribution.

THE issue by the Meteorological Office of the daily charts of the weather in the northern hemisphere has enabled me to ascertain the barometric changes which take place from day to day in high latitudes. As a rule, the cyclones and anticyclones are large as compared with the polar uncharted area, and it proved possible to extend the isobars of the surrounding areas over the Arctic Sea. However, east Siberia could not, in the absence of the Japanese daily charts, which reach England about six months late, be dealt with.

From the partially completed charts the mean pressures were calculated for each day along latitudes 30°, 40°, 50°, 60°, 70°, and 80° north. When plotted they showed irregular periodic variations, some of which had a swing of something more than 25 days. As this is about the apparent period of rotation of the sun and pointed to our chief luminary as the cause of the variability of pressure from day to day, I decided to consider the sunspot question carefully.

By the courtesy of the Astronomer Royal, I have been supplied with bromide prints for each day for January, February, March, and April, and been allowed to see some of the later negatives of the solar disc. Also, by the courtesy of the director of the Meteorological Office, I have obtained the pressure charts—issued to the public, since March—for January and February.

The sunspots have been plotted upon a diagram, the abscissæ of which are days and the ordinates degrees on the sun's surface measured from the apparent centre of the disc. They clearly show the movements of each spot or group of spots, as they approach or recede from the centre of the disc, owing to the sun's rotation.

An examination of this diagram demonstrates the fact that the pressure is low over the Arctic regions when there are sunspots near the sun's centre, and that there are high pressures over the Arctic regions when there are no spots near the centre of the disc. Such low pressures due to sunspots occur in the long Arctic winter quite as markedly as they do during the summer. When the sun's disc was clear in the centre on April 24, the mean pressure north of 60° was 1025 millibars. On Mar. 8 the mean pressure was 1001 millibars and there were spots near the sun's centre.

I hope to be in a position to publish full details concerning the matter soon after the receipt of the Japanese weather charts of the North Pacific area for June.

Theories of Terrestrial Magnetism.*

By Dr. F. E. SMITH, C.B., C.B.E., Sec.R.S.

EARTH'S MAGNETIC FIELD AND SECULAR VARIATION.

VERY valuable criteria have been given by Gauss and by Schuster, the former showing that the main origin of the earth's magnetic field is within the earth, and the latter that the cause of the daily variations is external to the earth's surface. Any predominant magnetic effect due to external causes need not, therefore, be looked for.

What do we know of the so-called permanent field ? Examination of the available data leads to the conclusion that the magnetic field may be regarded as moving westwards along a parallel of latitude at the rate of a few seconds of angle per day, the rate of movement being such that, if continued for some hundreds of years, the field would make a complete revolution round the earth, the motion being in the opposite direction to that of the earth's rotation. The secular variation may therefore be regarded as caused by change in direction of the axis of magnetisation. If outer space is a conducting medium, there will be relative motion between the magnetic field of the earth and it, and the moving field will induce currents in the outer conducting medium, and these currents in turn will react and induce other currents and associated magnetic phenomena. There will also be mechanical reactions, and Schuster showed how these reactions can be calculated. It is certain that the induced currents must tend to destroy the motion of the inducing field, and that one effect must be to reduce the period of rotation. Such a reduction in the period of rotation would result even if the magnetic axis coincided with the axis of rotation, but when the two axes do not coincide there is another retarding couple acting on the magnetic field.

A circular movement of the magnetic pole about the axis of rotation may be regarded as produced by two radial movements at right angles operating from that axis. Such motions of the magnetic field will induce currents in the conducting layer, and the reacting forces will tend to destroy the movements which produce them, that is, the tendency will be to make the two axes coincide. The total result is, therefore, to slow down and eventually destroy the rotation of the magnetic axis and to reduce the angle of separation of the two axes and eventually cause them to coincide. A bird's-eye view of the magnetic and geographical poles taken over a long period of time would reveal a spiral path for the magnetic pole, the latter drawing nearer and nearer to the geographical pole.

It is, of course, not necessary to assume a large volume of outer space to have uniform conductivity to produce such effects. An outer layer will suffice, and the conductivity may be uniform or patchy, but the reactions will be of the sign indicated. It is certain that the movements of the magnetic field are not simple as outlined above but are very complex, and that unexpected reversals occur, so that it is not possible to predict the conditions even twenty years ahead. The theory advanced is, however, still capable of explaining the variations, for any conducting layer may not only vary greatly over considerable areas, but there may be relative motion between the earth and portions of the layer which also varies.

ELECTRIC CURRENTS CIRCULATING ROUND THE EARTH.

The next simplest theory to that of a magnetic core is that the magnetic field is due to electric currents circulating round the earth, and this naturally gives rise to the question of the seat of origin of the electromotive forces necessary to maintain such currents. If the currents are uniform in density throughout the volume of the earth, the magnitude of this density would be about 10^{-8} amp. to produce the necessary intensity of magnetisation. If we suppose that there was once a source of electromotive force but it has long ceased to operate, the currents produced would take a very long time to die down owing to self-induction. But it is much more profitable to look for a possible electromotive force not only to produce but also permanently to maintain a current system.

Such a possible source was indicated by Larmor at a meeting of the British Association in 1919. Larmor pointed out that in the case of the sun, surface phenomena indicate the existence of a residual internal circulation mainly in meridian planes. If this circulating conducting material cuts a magnetic field which in direction is the same as that of the earth, circulating currents will be set up in such a direction as to augment the magnetic field, and eventually a condition of equilibrium will be set up between the producing electromotive force and the attenuation effects. The system is, in fact, that of a self-exciting dynamo, and the energy of the system is obtained at the expense of the energy of the circulating conducting material.

While in the case of the earth any internal circulation of matter in meridian planes or near thereto is entirely conjectural, the theory does provide not only for the main field but also for the secular variation by changing the paths of the circulating currents.

Ross Gunn has recently put forward a theory attributing the magnetic field to electrical currents set up inside the earth in the high temperature regions where the thermal motions are considerable. Gunn suggests that the temperature of the inner earth is of the order of 10,000°, and as a consequence the material will be highly ionised and the conductivity correspondingly great. In the case of the upper atmosphere, Gunn has analysed the motions of ions and electrons of long free path spiralling about the magnetic lines of force, and in such a case a diamagnetic effect and drift currents are produced.

* From the presidential address to Section A (Mathematical and Physical Sciences) of the British Association, delivered at Bristol on Sept. 8.

An extension of the calculation to the inner earth where the free paths are short is made, and it is considered that the primary current system of the earth results from the motions imposed upon ions having a mean free path of the order 10^{-7} cm., the motion being imposed by the internal gravitational electric field at right angles to the magnetic field. The currents produced augment the original field in a regenerative manner.

MAGNETIC EFFECTS ASSOCIATED WITH EARTH'S ROTATION.

Let us consider the possible ways in which a body may by virtue of its rotation act like a magnet. First consider the earth as a body carrying a positive or negative electric charge. If the surface density of the charge be ρ, the magnetic force at the equator parallel to the surface is

$$H_e = \frac{4}{3}\pi\rho r\omega$$

where ω is the angular velocity and r the radius of the earth. If Q is the total charge on the surface, the horizontal magnetic force may be written

$$H_e = Q\omega/3r = \frac{V\omega}{3}$$

where V is the potential. In this case it is obvious that any small sphere charged at the same potential and rotating at the same angular velocity would produce the same surface field, since the radius of the sphere is not involved.

If, however, the charge be distributed uniformly throughout the earth—and this is necessary for uniform intensity of magnetisation—the value of the horizontal field at the equator is $Q\omega/5r$. If the charge on the earth be negative, the resultant field is such that there would be an upward vertical component at the north pole, and a south to north horizontal field at the equator. A field of this type does not exist in practice, the field of the earth being such that its direction is south to north at the equator and vertically downwards at the north pole. Moreover, it is not possible to produce by means of a single rotating charge, fields of the correct sign both at the pole and the equator, for if we change the sign of the charge the resultant fields at pole and equator are also changed in sign.

To overcome the difficulties of a surface charge, Sutherland suggested an equal but opposite charge concentrated at the centre of the earth, thus neutralising the electrostatic field due to the surface charge but not the magnetic effect of the charges in motion. Later he suggested that an inequality in the distribution of the earth's atomic charges might be a cause. There are a number of variants of this idea of separated charges. One is that the rotation of the earth brings about an electric polarisation in the atoms perpendicular to the axis of rotation, such polarisation producing a magnetic and also an electrostatic field. The direction of magnetisation of the field is not, however, that actually observed on the earth, the same difficulty presenting itself as that already considered with the charged sphere.

In 1891, and on several occasions since, Schuster has raised the question whether every large rotating mass is not a magnet, and so far back as 1891 he put forward the suggestion that the sun has a magnetic field associated with it.

The observed similarities between the magnetic fields of the earth and the sun, especially as the physical conditions are so different, naturally lend support to the theory that the magnetisation is brought about by rotation, and the fact that the axes of rotation and magnetisation do not coincide, while disturbing, may possibly be explained by reasonable assumptions.

If rotation of matter is necessary to produce the magnetic fields of the earth and the sun, the angular velocity, the radius, and the density must be important factors. If the magnetic effect is proportional to $D\omega r^2$, where D is the density, the calculated intensity of the sun's field agrees with that observed, taking the earth's field as the standard. Unfortunately, owing to the square of the radius being involved in the expression for the field, an effect proportional to $D\omega r^2$ cannot be tested by experiments in the laboratory, as a value of ω necessary to produce a measurable effect could not be obtained. A magnetic effect proportional to $D\omega r$ can be and has been tested in the laboratory, but the effect is far too small to account for the earth's magnetism.

A theory which has been tested by laboratory experiments is one depending on gyroscopic action. If the magnetic condition of iron arises from the rotation of the electrons in the constituent atoms, the axes of rotation should tend to become parallel to the earth's axis of rotation. The net result so far as the magnetic effect is concerned is to cause each molecule to contribute a minute magnetic moment parallel to the earth's axis of rotation. The effect will be proportional to the angular velocity and not the radius, so that the effect can easily be tested in the laboratory. Barnett first succeeded by laboratory experiments in showing that magnetisation was produced in this way and that the intensity of the field observed was proportional to the angular velocity. The direction and general shape of the magnetic field of the earth could be accounted for by this gyromagnetic theory, but the intensity of magnetisation produced is far too small. The estimated value is about 10^{-11} times that of the earth.

POSSIBLE MODIFICATION OF LAWS OF ELECTRODYNAMICS.

The difficulties confronting such theories as an electrically charged earth and the smallness of the gyromagnetic effect, have led to suggestions that the field may be due to some departure from the commonly accepted laws of electrodynamics.

In 1894 J. J. Thomson pointed out that if atoms exerted slightly different attractions on positive and negative electricity, then a large rotating body could produce a magnetic field. In such case the intensity would be proportional to ωr^2, so that no laboratory experiments could confirm or refute the theory.

Swann, who has put forward a theory based on a slight modification of the laws of electrodynamics, points out that the ratio of the magnetic fields for the earth and sun would be obtained also for an expression of the form $D\omega^4r^4$, since the ratio of the values of ω^4r^4 differs inappreciably from that of ωr^2. According to this theory, spheres of such size that they may be used in laboratory experiments should give effects which are just measurable, and Swann and Longacre have made experiments with a copper sphere 10 centimetres in radius rotating at 200 revolutions per second, but the results obtained differ very appreciably from those calculated on the theory, that is, an effect proportional to ω^4r^4.

VERTICAL ELECTRIC CURRENTS.

There is, however, a possibility that a small portion of the earth's magnetic field may be due to vertical electric earth-air currents, which can easily be distinguished from currents circulating in the upper atmosphere or in regions beyond.

Rücker chose areas in Great Britain where the magnetic forces were well known, and failed to find any evidence of such vertical currents. Dyson and Furner made an examination of data available in 1922, and conclude that although there is some evidence, such currents are not indicated with any certainty. On the other hand, Bauer has made many calculations, and on all occasions has been forced to conclude that such vertical currents do exist.

The probable error, however, associated with the measurements is considerable; but sufficiently precise measurements could be made over a carefully chosen area which would enable a definite decision to be reached with respect to such vertical currents.

DAILY VARIATIONS.

Schuster's analysis shows that the daily variation is probably due to electric currents in the upper atmosphere, but in addition to the magnetic effects of these currents there is an effect due to currents induced in the earth by them. These induced currents are naturally in the opposite direction to the inducing ones, and hence the magnetic effects for the horizontal intensity are additive, while those for the vertical force are opposed.

Chapman's analysis shows the system in the sunlit hemisphere to consist of two closed circuits which (at the equinoxes) may be taken as symmetrical with respect to the equator, their foci lying very nearly on the 11 A.M. meridian. As the electric currents are supposed to be induced by the movement of conducting layers of air in the magnetic field, such currents must also be produced near the ground, but the conductivity of the air near the ground is so low that their effect may be neglected. In the upper regions the movements, while larger, cannot be regarded as immeasurably greater than near the earth's surface, and the increase in current intensity can only be attributed to an increase in the conductivity, a view which Balfour Stewart was forced to adopt, although at the time there was little evidence to support it.

The magnitude of the dynamo effect is dependent on three factors—(1) the horizontal movement of the air, (2) the conductivity of the air, (3) the intensity of the vertical magnetic field. All these factors vary with latitude, and hence it is to be anticipated that the magnitude of the variations will also vary with latitude, which is the case. The intensity of the field can be calculated with considerable accuracy but the conductivity and movements of the upper air are not known, although such movements are attributed to thermal effects and hence will be a maximum in the daytime.

As a first and crude approximation we may imagine a spherical conducting layer to surround the earth, and in addition a conducting hemispherical cap over the hemisphere facing the sun, the height of this cap being a few hundred kilometres. Neither the complete spherical conducting shell nor the hemispherical cap are of uniform conductivity, and the matter constituting these layers moves with the earth, so that ionisation and recombination are always taking place.

While we have from wireless measurements fairly good evidence of the height of the lower conducting layers, our knowledge of the extent of the ionisation is not sufficiently good to enable us to do more than speculate on the merits of the theories advanced, for in addition to the dynamo theory there is due to Ross Gunn known as the diamagnetic layer theory, and a third called the drift current theory. The differences between the theories are best brought out by considering the ionisation effects in the hemispherical conducting cap facing the sun. Pederson has calculated the number of electrons and ions per cubic centimetre at various heights and he and Ross Gunn have considered the nature and magnitude of the conductivity of the upper ionised regions. They have shown that the conductivity varies with the direction of the magnetic field, the conductivity at right angles to the fie being at times very small, and under certain conditions it approaches zero, while the conductivity in the direction of the field is unaffected by the field's intensity. Hence in layers where the conductivity transverse to the magnetic field is very small, such large circulating currents as are necessary for the dynamo effect cannot flow, and where there is an appreciable vertical magnetic field there can be but negligible horizontal electric currents. In the case considered by Gunn, where a charge in its spiral path can execute many revolutions between successive collisions, the spiral motion of the charge has the same effect as a small magnet opposed to the field, so that the whole hemispherical cap is equivalent to a diamagnetic layer, and to this diamagnetism Gunn attributes the diurnal variation. There appears to be no doubt that such a diamagnetic effect does exist, and that it contributes to the diurnal variations, but its magnitude is much too small to explain the whole of the diur variation.

Chapman has shown how the ionisation in the diamagnetic layer contributes far more effectively to the diurnal variation. He shows that the les the contribution made by a charged particle to the

ansverse conductivity (relative to the magnetic ld) the greater is the mean drift velocity which experiences, and in the case of the earth's mag- tic field such drift currents are eastward in direc- on. There is, in fact, a steady drift of electrons nd ions in a direction perpendicular to the lines f magnetic force and the gravitational field.

With regard to the relative merits of the three eories, an effect of the diamagnetic layer appears rtain, but with it is associated the drift current ffect which is much larger. The diamagnetic layer ffect must therefore be regarded as secondary in nportance. The dynamo theory involves motions f the air as well as ionisation, and while on the hole the drift current theory appears to be superior, ore information is needed of the number and istribution of ions and electrons in the upper tmosphere before coming to a final decision.

SUNSPOTS AND MAGNETIC STORMS.

Any unevenness in the radiation from the sun s it rotates must also affect the conductivity and ence produce variations. Examination of magnetic ecords shows that many variations are related to he sun's period and also to sunspot periods, and it ppears not improbable that there is overlapping f several periods probably intimately connected. results obtained show that with rise and fall f sunspot frequency there are corresponding hanges in the diurnal variation. Moreover, the mplitude of the daily changes rises and falls with he intensity of the magnetic disturbance. It lows, therefore, that change in amplitude of the iurnal variation in years of many sunspots is due the same ultimate cause, namely, solar radia- on, as that causing magnetic disturbance.

Magnetic storms are marked disturbances of ar origin, and to explain these many theories ve been advanced, but the facts are not easy of planation. One of the first theories put forward tributed magnetic storms to the magnetic fields duced by streams of charged particles from the n acting like an electric current and producing direct magnetic effect. Schuster showed that ch a stream moving between the sun and the h would move in a magnetic field of constantly creasing intensity, and would be subject to a tarding force also continually increasing. Linde- ann has overcome this difficulty by suggesting lar streams which are ionised but on the whole utral. The groups of particles are assumed to projected from the solar prominences, and the ises in these are of such high velocity, 10^8 cm. r sec., that the journey from the sun to the earth ould be possible in less than two days, without rious recombination taking place. Moreover, ing to its neutrality such a stream will not tend spread outwards by the mutual repulsion of its nstituent particles.

Maris and Hulbert attribute the increase in nsation to the action of ultra-violet light. They nclude that at heights of 300-400 kilometres mperatures of 1000° K. are reasonable, and at ights exceeding 400 kilometres the free paths the particles are very long, the motions due to formal impact considerable, and the ionisation entirely due to the action of ultra-violet light. When the activity of the sun increases it is assumed that there is a tremendous increase of ultra-violet light; thus Maris and Hulbert estimate that if one ten-thousandth part of the solar surface (temperature 6000°) were removed and there were exposed regions of black body temperature 30,000°, the total ultra-violet energy would be increased 10^5 times, whereas the solar constant would be increased by only 1 per cent.

Recently Chapman and Ferraro have suggested that magnetic storms are essentially connected with the approach of a neutral ionised stream towards the earth, the more important changes in the stream taking place in the direction of the sun at a distance equal to a few times the radius of the earth. Retardation of the stream results, and this retardation is naturally greatest at that part of the front of the stream in direct line with the centre of the earth. On either side the stream will advance and partly enclose the earth, and along the sides of the enclosure there will be charged layers due to the polarisation of the stream by the magnetic field. Across the space on the dark side of the earth it is assumed that a westerly current is set up due to charges passing over the space between the charged layers.

NEED FOR MORE PRECISE DATA.

This very hasty sketch of some theories relating to terrestrial magnetism reminds me of Dr. Chree's remarks that the deductions from such theories are just as hypothetical as the theories themselves, and I am very sensible that this rapid survey is not only incomplete, but also that no theory considered is completely satisfactory. Moreover, while fully realising that they are vital links in any chain of evidence, I have avoided the companion subjects of auroræ, atmospheric electricity, and earth currents, because to have considered them would have taken far too long. I do, however, wish to emphasise that data of a precise kind are much needed to modify existing theories and to produce new ones, and I cannot do better than conclude with a remark of Rücker's in Bristol thirty-two years ago. Rücker said: "If there be any who are inclined to ask whether the careful study of terrestrial magnetism has led, or is leading, to any definite results, or whether we are not merely adding to the lumber of the world by piling up observations from which no deductions are drawn, we may answer that, though the fundamental secret of terrestrial magnetism is still undiscovered, the science is progressing. . . . But there are special and cogent reasons why the science of terrestrial magnetism should be cosmopolitan. For those who would unravel the causes of the magnetic movements of the compass needle concerted action is essential. They cannot, indeed, dispense with individual initiation or with the leadership of genius, but I think that all would agree that there is urgent need for more perfect organisation, for an authority which can decide not only what to do but what to leave undone."

The Fifth International Botanical Congress.

NEVER has there been such a large and representative gathering of botanists as was assembled in Cambridge on Aug. 16–23 for the Fifth International Botanical Congress. Of the twelve hundred members who registered, nearly one thousand attended. As was to be expected, Great Britain supplied most members, but the United States of America sent a large contingent, and, including the overseas portions of the British Empire, about fifty-five peoples were represented. The original intention had been to hold the Congress in London, but it was decided that Cambridge would be a more convenient centre.

London, however, shared in the programme. The Linnean Society generously supplied a reception room at Burlington House for the two days preceding the meeting at Cambridge, and threw open its rooms to members of the Congress. In addition, a selection from the Linnean collections was exhibited and members were presented with a descriptive catalogue, which also included an account of the foundation and history of the Society. The story of the efforts of the younger Linnæus to prevent the sale of his father's collections and to preserve them from deterioration; of their offer by his mother to Sir Joseph Banks after her son's death, in order to provide suitable marriage portions for her daughters; of their purchase at Banks's suggestion by James Edward Smith; of the foundation of the Linnean Society and its early meetings at Smith's house in Great Marlborough Street, where the collections were for a time housed; of their subsequent homes, including for many years Sir Joseph's house in Soho Square, until their arrival at Burlington House in 1857; and of their purchase from Smith's executors at a price ruinously increased beyond the original cost, is well told in the pamphlet, which overseas members will value as an interesting memorial.

On the Friday evening a reception was held at the Imperial Institute, where the members were received on behalf of His Majesty's Government by the Right Hon. Christopher Addison, H.M. Minister of Agriculture and Fisheries.

At Cambridge many of the members were accommodated in the colleges, a privilege which was evidently much appreciated, especially by American visitors. The sunny weather which lasted through most of the week showed Cambridge at its best.

The business of the Congress opened with a plenary meeting in the large Examination Hall at Cambridge, where the members were welcomed, in a Latin speech, by the Vice-Chancellor of the University, in state, and by the president of the Congress, Prof. A. C. Seward. At a second plenary meeting on the following Wednesday, two hundred delegates conveying greetings from governments, departments of state, universities, societies, and institutions were presented to the president. At this meeting also Prof. F. A. F. C. Went, of Utrecht, presented an invitation to Holland for the next Congress, to be held in 1935. The invitation was unanimously accepted. Morning and afternoon throughout the week were devoted to sectional meetings, the business closing with a plenary meeting at noon on Saturday.

Apart from the value of the papers and discussions in the sectional meetings, which were well attended, the Congress afforded ample opportunity for intercourse among fellow-workers from all parts of the world. Old friendships were renewed and colleagues known only by correspondence or exchange of papers took human shape, and the reception room (always a centre of activity), social meetings, excursions, and meals in common in the old college halls were media for conversation, discussion, and exchange of ideas.

Serious work was distributed among eight sections—bacteriology, phytogeography and ecology, genetics and cytology, morphology and anatomy, mycology and plant pathology, plant physiology, palæobotany, and taxonomy and nomenclature. A volume of abstracts of the communications, a copy of which was given to every member, facilitated the work of the sections.

An important duty of the Congress was to review the rules of botanical nomenclature. The code of rules formulated at the previous Congresses at Vienna (1905) and Brussels (1910) had been re-examined by an international committee appointed for the purpose at the previous Congress held in America in 1926. The function of the committee was to receive and report on suggestions and resolutions submitted by botanists generally, and the results of its deliberations in the form of a Synopsis prepared by the Rapporteur-général, Dr. John Briquet of Geneva, formed the basis of discussion by the Sub-Section on Nomenclature. It was hoped that certain differences in practice, and more especially the fundamental differences between the majority of workers on one hand and a school representing an important section of American botanists on the other, might be amicably settled, and that the 1930 Congress might witness the achievement of a system to which workers generally would be willing to conform. Pleasing features of the discussions were the evident wish to arrive at a common agreement and the absence of that somewhat polemic atmosphere which was noticeable at Vienna in 1905. Dr. E. D. Merrill, Director of the New York Botanic Garden, presided over the meetings, and, guided by the Rapporteur-général and other experts, the sub-section was able to formulate a revision of the Vienna and Brussels "Rules" which was adopted at the final plenary meeting of the Congress and left to an editorial committee to prepare for press. Especially helpful in securing this revision were the suggestions contained in a code drawn up by the British sub-committee appointed at the Imperial Botanical Conference in 1924, and a series of amendments to the international rules presented by Mr. Rehder, of the Arnold Arboretum.

An important outcome of the discussions on nomenclature was the appointment of a representative International Advisory Committee, to hold

office until the next Congress, which would adjudicate on debatable points in the interpretation of the rules. In the course of the debates the starting-point for the various groups evoked some discussion. While 1753, the date of the first edition of Linnæus's "Species Plantarum", was generally accepted for flowering plants and ferns (excepting fossil plants), later dates were suggested for some groups of cellular plants. To avoid upsetting well established names of genera by the strict application of the law of priority, the principle of lists of *nomina conservanda* was accepted for all groups. The scrutiny of these lists was to be a function of the Advisory Committee. The principle of similar lists of conserved names of species was rejected by a large majority.

Battle was joined afresh on the question of a compulsory Latin diagnosis when describing a new genus or species. The original alternative of the three best-known European languages is no longer tenable with the increasing spread of the study of taxonomy, and the only alternative to Latin was obviously the use of any tongue, a practice which would add to the difficulties of taxonomic work. It was also pointed out that the embodiment in a short diagnosis of the salient points of a genus or species would be helpful both to the author and other workers. The vote on the question indicated an almost complete disappearance of the opposition to Latin; an appeal from bacteriology and palæobotany to be excepted owing to inherent difficulties was, however, allowed. In order to legitimise names already published in a vulgar tongue, the rule will not come into force until January 1932. Another decision was the recognition of standard-species in fixing the identity of genera.

A discussion on methods of furthering the advance of taxonomy emphasised the importance of a broader training for the taxonomist and especially the value of a phylogenetic view-point. The formation of an International Taxonomic Bureau to assist and correlate systematic work and to relieve individual institutions of certain extraneous duties was also adumbrated. The question of finance was a serious factor. The species-concept was the *motif* of joint discussions, with the geneticists in relation to cytogenetics, and with the ecologists in relation to geographical distribution. The ecologists also considered standardisation in description and terminology in the study of vegetation-areas and plant-communities. The morphologists returned to two favourite subjects of discussion, the shoot-unit and the origin of the leaf, and floral organisation with special reference to the carpel. The mycology and plant-pathology section discussed the effect of environment on disease, plant-viruses (with the bacteriology section), and the dissemination of cereal rusts; in connexion with the last-named a resolution was formulated asking the co-operation of overseas governments in the study of these pests of cereal crops. The plant physiology section dealt with protoplasmic organisation and the cell, and problems of growth and nutrition; and the palæobotany section, the antiquity and origin of angiosperms, early terrestrial vegetation, and plants as stratigraphical indices. Life-cycles of bacteria and criteria for differentiation were subjects of debate by the bacteriologists.

In connexion with the various sections, exhibits and demonstrations germane to the discussions were arranged. Evening lectures, including a topical one by Mr. G. F. Hickson on the University of Cambridge and its Colleges, and other subjects of general interest, provided a change from the more specialised work of the sections, which with their differing technicalities of language recalled, as Prof. von Goebel remarked, the Tower of Babel.

The honorary degree of doctor of science was conferred by the University of Cambridge on Dr. John Briquet, Director of the Geneva Conservatoire and Botanic Garden; Prof. Ludwig Diels, Director of the Botanic Garden and Museums at Berlin; Prof. T. G. Halle, Keeper of Palæobotany in the Swedish Natural History Museum; Prof. L. R. Jones, of the University of Wisconsin; Prof. C. J. Schröter, a pioneer in ecology, and Prof. F. A. F. C. Went, Director of the Botanic Garden and Laboratory at Utrecht; and (in absence) Prof. P. A. Dangeard, of the Paris Museum.

Social functions included a garden party by the president and Mrs. Seward in the grounds of Downing College, a reception by the Master and fellows of St. John's, and a dinner in the hall of Trinity College, where overseas delegates were entertained by their British *confrères*. Among the excursions were a whole-day visit to Wicken Fen. A select party visited Halesworth, Suffolk, where a memorial tablet to William and Joseph Hooker was unveiled by Sir David Prain (see NATURE, Aug. 23, p. 287).

Though the business of the Congress finished on Aug. 23, many members availed themselves of excursions and visits arranged from London in the following week. These included visits to Darwin's House at Down, Kent; the Rothamsted Experimental Station; the Royal Horticultural Society's Gardens, Wisley; the John Innes Horticultural Institute, Merton; and the nurseries of Messrs. Sutton and Carter. The Director and members of the staff of the Royal Botanic Gardens, Kew, received the visitors on Monday; and a special exhibit was arranged at the Department of Botany, British Museum, where the keeper and his assistants were in attendance on two afternoons. In connexion with the visit to the Museum a booklet had been prepared explanatory of the exhibits and giving an account of the origin and growth of the botanical collections since the foundation of the Museum as the result of the bequest of Sir Hans Sloane's collections in 1753. Of special interest to overseas visitors were volumes from the Sloane Herbarium containing the early collections from Jamaica and other parts of the New World, and the original specimens which were the basis of Linnæus's first great systematic work, the "Hortus Cliffortianus", and of his "Flora Zeylanica" (1747).

For the success of the Congress and the smooth working of the arrangements in Cambridge and London, special thanks are due to the secretaries, Mr. F. T. Brooks and Dr. T. F. Chipp, and their willing helpers.

The British Association and a Centenary Fund.

IN 1931 the British Association for the Advancement of Science will hold its centenary meeting in London. No more appropriate place of meeting could have been selected. The Association may justly claim to be fully representative of science as a whole within the British Isles; by its overseas meetings it has stimulated scientific activities and focused the aims and interests of scientific workers in the dominions and dependencies. This dual function makes it inevitable that so momentous an occasion in its history should be endowed with a significance which can most fittingly find expression only in the capital city of the Empire.

The imperial character of the meeting and the place in which it is to be held will make serious demands on the organisation and resources of the Association. On normal occasions the annual meeting is a heavy burden, financial and otherwise, on the locality in which it is held. In London expenditure will be altogether on a higher scale. The cost of entertainment of foreign guests and visitors from the dominions and dependencies, if it is to be such as will be regarded as commensurate to the occasion, will be far beyond anything the Association has been able to contemplate hitherto. Without entering into detail, it is abundantly clear that the financial resources of the Association, derived as they are largely from subscriptions which are liable to fluctuation and on ordinary occasions provide no very large margin over the expenses incurred, cannot be relied upon to produce the sum which will be required.

The British Association, having this in view, proposes to raise a fund for its centenary which will be sufficient to meet necessary and desirable expenditure for the meeting. But, in addition, it asks for a sum which will place its finances on a basis adequate for the future development of the Association's approved activities. The appeal was launched at the opening of the recent meeting at Bristol. Everyone connected with scientific work in Great Britain would surely wish that the centenary of the Association should be celebrated with the dignity and circumstance befitting the occasion; but it is perhaps only those who have been intimately in touch with the inner working of the Association who will appreciate fully all that is implied in the reference to the future development of its work.

During the hundred years of its existence, the Association has striven for the advancement of science primarily by promoting intercourse between scientific workers through its annual meetings. By encouraging the attendance of those not specifically engaged in scientific work or even not specially trained in any one branch of science, the Association has endeavoured to extend the interest in science among the public, especially when occasion offers in regard to its practical application to the affairs of everyday life. While a larger public has been made aware of this side of the Association's work through the good offices of the daily press in reporting the proceedings in the sections and at general meetings, it has had little opportunity to appreciate the valuable support given to research by the money grants administered through research committees. These grants, made year by year on the nomination of the sectional committees representative of the various sciences comprised within the Association, constitute one of the greatest, if not the greatest, of its services in the advancement of science. Many of the committees have produced results of national and even international importance. Even though the sources outside the Association from which grants for research are available have increased in recent years, the assistance of the Association is still in demand, especially in the initial stages of research. At the present moment, indeed, the Association maintains some seventy research committees distributed among the various sciences. For some years the Association has disbursed an average annual amount of £1100 on the work of its committees—a sum expended entirely in the actual cost of research, the members of the committees receiving no remuneration for their work. The amount available for these grants is to a great degree dependent upon the amount of the subscriptions received, and in the past has frequently been inadequate to the demands.

It is probable that the public is not aware that the activities of the Association are not confined to the duration of each annual meeting. In the interval between sessions the organisation of the Association is not even solely engaged in preparing for its next meeting, heavy as is the work entailed thereby. The Council is also occupied in giving effect to the resolutions passed at the preceding annual meeting, which are usually of considerable moment and, as they frequently affect public interests or policy, involve the submission of the resolutions to Government departments, administrative bodies, and kindred societies. Further, the Council may be said to hold a watching brief for science throughout the year. It is prepared to take action, if need arises, in all matters in which science may be directly or indirectly affected.

While other aspects of the Association's work must here be passed over, reference may be made to the Association's custody of Down House, the home of Darwin, which will in future entail no inconsiderable expense.

The annual income of the Association at the moment is about £5600, of which nearly a half is derived from the fluctuating annual subscriptions. The amount at which the Association aims for its fund has been put at £40,000. If from the sum raised part is added to endowment, the Association will be placed in a position to assure its activities and extend them in directions which cannot fail to be of advantage to science. In particular, the amount available for research will be increased; the burden of the annual meetings, now so heavy on the place of meeting, may be somewhat lightened, and the imperial obligations of the Association,

which have come increasingly into prominence of late years, may be more adequately met.

It should be scarcely necessary to press the claim of the Association in further detail. The position which it has won by its work during the past hundred years is a sufficient warranty of its deserts and of its fitness to administer wisely any funds committed to its charge. On the ground of its services to science and to the community, the Association has well earned the right to expect the support for which it asks.

The greater part of the Bristol meeting of the British Association was favoured by fine weather, of which full advantage was taken by all the sections. Owing to the easy access of many points of special interest, these purely sectional excursions were more fully organised than is usually the case. The Norman Lockyer Observatory at Sidmouth was visited by a party of physicists and astronomers, while Wookey Hole and the Mendips attracted geographers, zoologists, geologists, and anthropologists. The Forest of Dean was included with other excursions by botanists. In the sections themselves, apart from the presidential address, physicists listened with great interest to a summary of the present state of the theory of cohesion by Prof. Lennard-Jones, who showed that through the new mechanics a most promising theory is at last in the process of development. The subject of the present position of the British dyestuff industry provoked an important discussion in Section B, to which many well-known academic and industrial chemists contributed. The memorial lecture to Dr. Beddoe by Sir Arthur Keith emphasised the important anthropological work which has been and is still being done in Bristol, which Sir Arthur pleaded should be recognised by the foundation of a chair in that subject in the University. Airships, both British and German, naturally attracted engineers in Section G; while members had an opportunity of seeing the gyroplane in action at the new Bristol airport. The largest available theatre was filled for a joint discussion between geology, geography, and anthropology, on the relation between past pluvial and glacial periods, under the chairmanship of Prof. Fleure.

The following were included amongst the foreign guests present at the meeting: *Section A* (Mathematical and Physical Sciences): Prof. R. S. Mulliken (Chicago), M. R. Bureau (Paris), Prof. M. Siegbahn (Uppsala), Prof. Van Vleck (Wisconsin); *Section B* (Chemistry): Prof. J. H. Hildebrand (Berkeley, California); *Section C* (Geology): Prof. G. Delépine (Lille); *Section D* (Zoology): Prof. D. de Lange (Utrecht); *Section E* (Geography): Prof. A. E. Douglass (Tucson, Arizona); *Section G* (Engineering): Prof. A. E. Kennelly (Cambridge, Massachusetts); *Section H* (Anthropology): Prof. E. Fischer (Berlin-Dahlem), Dr. M. Vassitz (Belgrade); *Section K* (Botany): Prof. T. H. Goodspeed (Berkeley, California), Prof. D. H. Campbell (Stanford, California), Prof. W. J. V. Osterhout (New York), Prof. F. A. F. Went (Utrecht).

The total membership for the Bristol meeting was 2650.

The General Committee of the Association has approved the arrangements made by the Council for the centenary meeting to be held in London next year. The president will be the Right Hon. J. C. Smuts, and a long list of vice-presidents prepared by the Council, together with a representative London Committee, was also accepted by the General Committee.

As the Albert Hall will not be available for the inaugural meeting in London, the Council booked the Wesleyan Central Hall and annexes for this meeting. The General Committee approved of this and also of the proposal that the inaugural meeting should be devoted mainly to receiving addresses and other messages, the president-elect finally addressing the meeting. His presidential address will, however, be delivered on a separate occasion, namely, the final evening of the meeting, Tuesday, Sept. 29. The reception room, sectional meeting rooms, etc., will be in and near Exhibition Road, South Kensington, at such institutions as the University of London, Imperial College of Science, Imperial Institute Science Museum, Victoria and Albert Museum, Royal College of Music, and the Royal Geographical Society.

The new members of Council elected by the General Committee are: Prof. H. Clay, Prof. W. T. Gordon, Dr. C. W. Kimmins, Sir Peter Chalmers Mitchell, and Dr. H. T. Tizard.

The meeting of the Association in 1932 will be held at York, and in 1933 at Leicester. The Lord Provost of Aberdeen and the Principal of the University, Sir George Adam Smith, attended the meeting of the General Committee on Sept. 5 to invite the Association to meet at Aberdeen in 1934, and the invitation was unanimously accepted.

News and Views.

THE fact that definitely anti-social actions have been committed under the cloak of rationalisation is responsible for many of the misgivings with which labour regards the rationalisation of industry. Moreover, the displacement of workers by machinery has led to some distrust of science by labour. Labour-saving machinery is too often labour-displacing machinery, and although mechanical science is gradually eliminating from industry many of the most unhealthy and exacting conditions of labour, notably in the mining and metallurgical industries, science is often held responsible for creating unemployment. Labour frequently fails to realise that originative discoveries of science create new demands and open fresh avenues of employment in which displaced labour is absorbed. Such discoveries are, of course, those with which science is most closely associated. In this connexion, addresses such as that given by Sir Richard Gregory on Sept. 7, in connexion with the Bristol meeting of the British Association, before the Bristol Branch of the

Independent Labour Party on "Science and Labour", are particularly valuable at the present time as tending to bridge a gulf which, since the days of Darwin, Huxley, and Kingsley, has gradually developed between science and labour.

SIR RICHARD GREGORY referred in his address to the development from fundamental scientific discoveries, such as those of Faraday and Cavendish, many of which were regarded as of no practical value when made, of a wide range of new industries—electrical engineering, the fixation of atmospheric nitrogen, automobiles, aviation, metallic filament lamps, the gramophone, and the many branches of wireless telephony. In every one of these cases the application of scientific discovery has resulted in increased employment and frequently has been accompanied by an increase in the pleasures of life. It may well be that the future of civilisation largely depends on the ability of science once again to co-operate with labour. Unsatisfactory social conditions are often a consequence of incapacity to use aright the results of scientific advances. Such incapacity is frequently due to the political impotency of scientific workers and their failure to co-operate, and the re-establishment of harmony between science and labour would do much to remove that political weakness. Such co-operation and harmony can, however, only be achieved by scientific workers demonstrating, as Sir Richard Gregory does in his address, that science is not merely mechanical invention but rather creative knowledge which enables man to control his environment, and by their participation in social movements as citizens whose motives are above suspicion and whose knowledge is at the service of the community for the promotion of the greatest good.

PROF. T. E. GREGORY's presidential address to Section F (Economic Science and Statistics) of the British Association, on "Rationalisation and Technological Unemployment", which was read in his absence on Sept. 8, is welcome indication that the Association recognises not only a duty to inform the general public on all scientific advances but also a corresponding obligation to assist in the control and solution of some of the problems created by such discoveries and their applications. The international character of the rationalisation movement and its undoubted effect in most cases in reducing the cost per unit of output make it impossible for any single country engaged in international trade under competitive conditions to contract out of its consequences except at the expense of its international trade. Since rationalisation effects a lowering of real costs, given a desire for a rising standard of life, Prof. Gregory believes there is no reason to suppose that the volume of unemployment will not again fall. The most optimistic view of the situation, however, must recognise that a grave transfer is involved and the difficulties may be accentuated by monetary and other independent circumstances. Scientific workers have no right to delude themselves into thinking that a new era of orderliness will come automatically, and must concern themselves much more seriously about the use or misuse of the new knowledge they have acquired and the social consequences of the improved methods of production which mechanical invention has developed. Increased productivity may tend to enhance the problem of unemployment, even if only temporarily, but it provides society with the margin of lower prices and increased leisure out of which unemployment can be relieved. The better use of the arts of production made possible by scientific methods and investigations is unlikely to endanger the organisation of society unless the process is applied with a wanton disregard of the injury which may be inflicted upon other industries or upon the workers rendered superfluous.

SIR ARTHUR KEITH's Beddoe Memorial Lecture, which was delivered in the course of the meeting of the British Association at Bristol, and of which we print a summary elsewhere in this issue, was an eloquent affirmation of the enduring value of the work of this great pioneer. Beddoe's originality and vision, as well as his patience in inquiry, place him in a rank apart among the greatest of the anthropologists of the nineteenth century. It was only fitting that Sir Arthur should couple his appreciation of Beddoe with a strong plea for the institution of a chair of anthropology in the University of Bristol. The work of the Spelæological Society has shown that enthusiasm for the subject and the true spirit of inquiry are there among the members of the University. Bristol presents opportunities for anthropological investigation that are unrivalled. As a gateway of Britain from the earliest times to the present day it holds a key position. The caves of the Mendips; the lake-villages of Glastonbury and Meare; the traditions of early contact with Ireland, hostile and otherwise; the ethnology, archæology, and folklore of the border counties of Wales—these are some only of the fields in which we should look to the University for enlightenment. Of the practical considerations in relation to civic affairs upon which Sir Arthur touched it is unnecessary to enlarge. To a public-spirited business community such as the City of Bristol, they should carry conviction without further emphasis.

THE report submitted at the Bristol meeting of the British Association to Section D (Zoology) by the subcommittee appointed to inquire into the position of animal biology in the school curriculum is, on the whole, encouraging: for there is evidence that biology is receiving wider recognition as a subject of educational value. It is a hopeful sign that a committee of the Economic Advisory Council has been appointed "to consider the obstacles which stand in the way of the education and supply of biologists for work in this country and overseas, and to submit recommendations for the removal of such obstacles". The British Social Hygiene Council, too, is pressing the claims of biology, and the Colonial Office is awake to the importance of the subject. All the examining bodies, with the exception of the Oxford and Cambridge Schools Examination Board, which is understood to have the matter under consideration, now provide syllabuses in biology for the school certificate examination. The percentage of candidates offering biology in this examination has been steadily

rising for the last seven years, and that of those offering botany as steadily falling. But unsatisfactory features in this report are the statements that the great majority of the biological candidates are girls, very few boys' schools taking biology in the school certificate examination; and that the shortage of men teachers with biological training persists. The vicious circle has not yet been broken down. The report suggests remedially the institution of general honours degrees, which four of our universities do already confer, by all universities as alternatives to the existing special honours courses. To this may be added the recommendation that all colleges in the residential universities should accept biology as a subject in their entrance examination. The refusal of some colleges to do so is a serious obstacle to the supply of biologists.

ON Sept. 5, Section B (Chemistry) of the British Association devoted the whole morning session to a discussion on the present position of the British dyestuff industry. Prof. A. G. Green, formerly director of research of the British Dyestuff Corporation, who opened the discussion, surveyed the position of the industry up to the time of the Dyestuffs (Import Regulation) Act, which came into force in January 1921 for a period of ten years. Since that date, the dyestuffs industry in Great Britain has made great strides; it now supplies 25,000 tons of dyestuffs annually, or about 11 per cent of the world's requirements. While the proportion supplied by Germany, Switzerland, and the United States has remained constant in the past few years, the British contribution has increased from 8·9 per cent in 1925 to 11·7 per cent in 1928. Prof. Green is of opinion that a further period of State assistance is both justified by past progress and by the present world position. Prof. J. F. Thorpe emphasised the need for the production of new dyes for new fibres coming into use, and referred in particular to the inevitable interdependence of flourishing schools of research in organic chemistry and a stable and vigorous dye-making industry. Sir William Pope also discussed the effect the Dyestuffs Act has had in promoting the training of chemists for all branches of industry. The industrial side was dealt with by Mr. J. Morton, of Scottish Dyes, who pleaded that the industry has justified the continuation of the Dyestuffs Act; but Sir Joseph Turner, managing director of the British Dyestuffs Corporation, urged that the Act has served its purpose and should be allowed to lapse.

THE third triennial conference of the Pathological and Bacteriological Laboratory Assistants' Association was held in the Medical School of the University of Manchester on Aug. 25–29. It was opened by Prof. W. H. Lang, pro-vice-chancellor of the University, who expressed appreciation of the skilled assistance rendered by the laboratory assistants in scientific work. Workers often do express their indebtedness to their assistants when contributing to the medical and scientific journals. Prof. Lang hoped that the time was close at hand when the laboratory assistants of other sciences would attach themselves to the Association. The following papers were read at the conference: H. R. Hardie (London), the development of chemistry, from alchemy to biochemistry; P. H. Osmond (Liverpool), the pathogen selective culture method; S. G. Laws (Uganda), a simple flocculation test for the diagnosis of syphilis; R. J. Bromfield (London), equipping a biochemical laboratory and selecting biochemical methods; D. B. Colquhoun (Glasgow), a new method of isolating the typhoid and paratyphoid group from fæces; A. H. Walters (London), the examination of rats for plague in the Port of London; F. Dale (Manchester), Vincent bacilli and spirilli in cervical smears. The subject for general discussion was the training of juniors, opened by Mr. J. McLean (London). Prof. W. Blair Bell welcomed the conference to Liverpool on Wednesday, Aug. 27, and also spoke on laboratory research in cancer investigations. At the conference dinner, Sims Woodhead memorial medals were presented to Prof. A. E. Boycott and to W. A. Mitchell (Cambridge) for conspicuous services to the Association. The attendance at the conference was representative of the widespread organisation, members attending from Uganda, north and western Ireland, as well as all parts of England, Scotland, and Wales.

THE hurricane that reached Santo Domingo on Sept. 3 last is said to have caused many thousands of deaths, to have practically obliterated the capital of the Dominican Republic, and to have given rise to wind speeds so great as 160 miles an hour. Accurate measurements of wind speeds so high as this are not likely to have been obtained, but the material damage done supports the view that speeds of exceptional magnitude even for a tropical cyclone occurred. The large death-roll was evidently due in part to the unfortunate chance whereby a populous city felt the full force of the storm at its height. According to Fassig, the mean path of West Indian hurricanes in September lies to the north of the Leeward Islands and near to the north coast of Haiti. The particulars received so far suggest that the recent storm, at least in its earlier stages, followed a path slightly to the south of the normal track, for Dominica (Leeward Islands) was mentioned as the first island to be affected, and suffered some loss of life, while most of the islands immediately to the north of Dominica were unaffected. It is to be hoped that the full figures for loss of life will not be found to be so great as for the Galveston hurricane that occurred on Sept. 8, 1900, when 3000 people were killed in that town alone, but they evidently do not fall far short of those for the earlier disaster. Even if the storm reaches the mainland with reduced intensity, as predicted, it will rank as one of the very worst in a record that goes back to the fifteenth century.

THE Russian Soviet Union Society for Cultural Relations with Foreign Countries has issued the first number (Jan.–Feb. 1930, pp. 120) of *V.O.K.S.*, an illustrated literary and scientific publication in English. The object of this journal is to acquaint readers abroad with current affairs and cultural development in Russia, and the first issue contains more than

thirty contributions. Most of these are signed articles of general interest, such as, "Women of the U.S.S.R.", by Sophia R. Farman; "Building a New State", by A. Gurowitsch; "Excavations in the Crimea" and "Culture over the Ether", by "E. L." There are also descriptive travel articles on Samarkand, Tadjikistan and Turkmenistan, but the present issue does not devote much attention to scientific matters, although Prof. B. Arendt describes the Soviet archæological expeditions in 1929 and an account is given of the Leningrad Institute of Experimental Medicine and of the work conducted at the laboratory for experimental biology in the Moscow Zoological Gardens.

THE Leningrad Institute of Experimental Biology has undoubtedly performed most valuable work for the Russian people during the last decade. Side by side with the investigations of Profs. Kravkov, Omelyansky, Pavlov, and Vinogradsky, much urgently needed routine work has been performed in connexion with hygiene and sanitation and the preparation and application of curative and preventive serums. Prof. Daniel Zabolotny, president of the Ukrainian Academy of Science and former Commissar for Public Health, was also connected with the Institute of Experimental Medicine until he died recently. An obituary notice of him appears next to an account of the medical research work in progress at Leningrad. Prof. Zabolotny will be remembered for his studies of plague epidemics and the rôle of rodents as carriers of disease. Attempts have been made in several of the contributions to emphasise the progress being made under the *P'atiletka* or five-year plan of economic reconstruction and industrialisation. This is exemplified by "The Non-Stop Week", an article illustrated by the new Russian calendar for January and February, in which there are eleven weeks of five days each—a scheme which, it is claimed, has added sixty working days to the year. It is announced that twenty issues of *V.O.K.S.* will appear annually, the subscription being six roubles, or 12*s*.

THE eleventh International Conference of the Apis Club was opened on Monday, Sept. 8, at 3.30 P.M., in the Apothecaries' Hall, kindly lent for the occasion by the Society of Apothecaries, by Lord Ebbisham, who laid stress on the desirability of promoting apiculture among small-holders and other land workers, and referred to the increasing appreciation in other lands of the work of the Club. Miss A. D. Betts, in her presidential address, recapitulated the history of beekeeping, showing how it appears to have attained its maximum of national importance among the worshippers of the mother-goddess in neolithic or bronze age times. It has gradually fallen to its low status of a century ago through the loss of its religious standing, and by the economic difficulties caused by the substitution of other beverages for mead, the diminution of the wax market at the Reformation, and especially through the effects of the use of sugar upon the demand for honey. She pointed out that modern apiculture is built up upon science and must remain allied with science if it is to prosper, and indicated some of the directions in which apiculture is, or could become, of national importance. The Conference continued throughout the week, Sept. 8–13, and included the reading of papers (at the Crystal Palace, in conjunction with the National Show of Bees and Honey) and an excursion to view the apiaries of Messrs. Sturges and Soden at East Dean, Sussex.

WE have lately received the first three Reports of the National Research Council of Japan. The first number is a reprint of one published in March 1922. The manuscript of the second number, and all the other materials, together with the office of the Council, were destroyed by the great earthquake and fire of Sept. 1, 1923. The issue of the later numbers has been delayed on this and various accounts, and the Council has now decided to bring out four double numbers in quick succession to cover the eight years, 1922–30, after which a single number will be published every year. The work of the Council is divided into eight sections, dealing respectively with astronomy, geophysics, chemistry, physics, geology and geography, biology and agriculture, medical sciences, and engineering, and each section issues its own *Japanese Journal*, except that astronomy and geophysics are combined in one, while that of biology produces separate journals of botany and zoology. The ideal that the Council has set before itself is that all original memoirs on one branch of science shall be published in the same periodical. Also, since papers written in the Japanese language are closed to western readers, authors are pressed to write either in English, French, or German, or if in Japanese to prepare full abstracts in one of these languages.

A CONFERENCE on steel structures research will be held in the lecture theatre of the Institution of Civil Engineers on Oct. 16 next. The purpose of the conference is to promote discussion of the work and objects of the Steel Structures Research Committee of the Department of Scientific and Industrial Research. This Committee has been set up to review existing regulations for the use of structural steel in buildings and bridges, and to investigate the possibilities of more efficient and economical design. In order to ensure the effective application of the results of the Committee's work, it is felt to be desirable at an early stage to enlist the interest and co-operation of various bodies concerned. The conference will, therefore, provide an opportunity for an exchange of views and for a consideration of various suggestions that have been made, in particular the feasibility of formulating a standard practice in the use of structural steel in building throughout Great Britain. Those interested are invited to communicate with the Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, S.W.1.

MESSRS. A. Gallenkamp and Co., Ltd., have written to us in connexion with the Research Item entitled "Electrical Heating in Laboratories" which appeared in NATURE of Aug. 30, p. 326. They have sent us lists No. 75 G and No. 231 F describing small electric furnaces and electrically heated laboratory apparatus which they have been making for several years. We think that apparatus of this type might

advantageously be more widely used in many laboratories in Great Britain. In several districts the cost of electricity has been largely reduced recently and the many uses of electrically heated apparatus should be more generally appreciated.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant teacher of nautical subjects at the Boulevard Nautical School and School for Fishermen, Hull —The Director of Education, Education Offices, Guildhall, Hull (Sept. 16). A bacteriologist and pathologist for the County of Lanark—The County Clerks, Lanarkshire House, 191 Ingram Street, Glasgow, C.2 (Sept. 17). An assistant bacteriologist for the City of Bradford—The Medical Officer of Health, Town Hall, Bradford (Sept. 18). A head of the Building Department of the Leeds Technical College The Director of Education, Education Department, Calverley Street, Leeds (Sept. 25). A lecturer in logic at Birkbeck College—The Secretary, Birkbeck College, Breams Buildings, E.C.4 (Sept. 25). A demonstrator in physics at St. Bartholomew's Hospital Medical College—The Dean, St. Bartholomew's Hospital Medical College, Smithfield, E.C.1 (Sept. 27). An assistant research and advisory officer in plant husbandry at the West of Scotland Agricultural College—The Secretary, Blythswood Square, Glasgow (Sept. 27). A principal of the Municipal Technical College, Bath—The Director of Education, Education Office, Sawclose, Bath (Oct. 7). A principal of the L.C.C. South-East London Technical Institute, Lewisham High Road—The Education Officer (T.1), County Hall, Westminster Bridge, S.E.1 (Oct. 11). An assistant in the Cancer Research Laboratories, Bristol Royal Infirmary—The Secretary, Royal Infirmary, Bristol. A Dr. Robert Pollok lecturer in materia medica and therapeutics in the University of Glasgow —The Secretary, University Court, The University, Glasgow. A research assistant, with degree in engineering, under the Research Association of British Motor and Allied Manufacturers—The Technical Secretary, Research Association of British Motor and Allied Manufacturers, 5 Bolton Road, Chiswick, W.4.

Our Astronomical Column.

Eros.—*Circ.* No. 296 of the U.A.I. announces that the first observations of the present very important apparition of this planet were obtained at Neubabelsberg by Dr. G. Struve, as follows:

1930.	U.T.	R.A. 1930·0.	N.Decl. 1930·0.	Mag.
Aug. 26^d	$0^h\ 55^m\ 30{\cdot}7^s$	$3^h\ 33^m\ 4{\cdot}13^s$	$34^\circ\ 25'\ 44{\cdot}6''$	11·8
27	23 44 18·6	3 38 22·47	35 0 35·6	

It was very close to the position indicated by a manuscript ephemeris prepared by Prof. G. Witt, who discovered the planet in 1898. Prof. Witt published an approximate ephemeris for the present apparition in *Mon. Not. Roy. Ast. Soc.*, vol. 85, No. 9. He gives a more precise one for October 1930 in *Astr. Nach.* No. 5729. The perturbations were computed partly by himself, partly by E. Noteboom; he notes that the 1928 observations show a puzzling discordance of some 3·5 sec. in R.A. Further search for its cause is postponed until after the present apparition. The distance of Eros from the earth is now just under a unit. It will be only one-sixth of a unit at the end of January. The magnitude will then be 7; it will be 9·6 on Nov. 1.

Rotations of the Stars.—A recent bulletin issued by Science Service, Washington, D.C., describes some investigations on this subject by Mr. C. T. Elvey at Yerkes Observatory. Provided that the axis of the star is not directed towards us, its rotation causes different portions of the star's surface to have different radial velocities. This produces a widening in the spectral lines. Mr. Elvey selected for examination the magnesium line at 4481, since it is normally sharp and narrow, so that its widening may be mainly ascribed to rotation. The contour of the line is studied by a microphotometer, which exhibits on a large scale the degree of opacity of each portion of the negative. If the whole of the widening of the line is correctly attributed to rotation, the majority of the stars studied are rotating much more rapidly than the sun. The mean rotational speed found for fifty-nine stars is 60 km./sec., about thirty times that of the sun; if a correction were introduced for limb-darkening, the value for the stars would be still greater. Drs. Shajn and Struve deduce that the variable star W Ursæ Majoris has a diameter of 650,000 miles, and rotates in one-third of a day. This, if correct, would produce great ellipticity of form.

Planets and the Sunspot Cycle.—There have been many attempts in recent years to find an explanation of the variations in solar activity by planetary action. The latest is by Mr. Luby in *Astr. Jour.* No. 943. He notes that several investigators have made out a good case for the influence of Mercury, Venus, and the earth on individual spots, but that, to explain the principal cycle we must look rather to the giant planets; the tidal action of Jupiter is twenty-three times as great as that of Saturn, which in its turn bears a still higher ratio to those of Uranus and Neptune. It seems, however, that the length of time through which they act in the same direction raises the action of these last-named planets to an appreciable amount. Mr. Luby contends that the true sunspot period is 11·86 years, agreeing with Jupiter's period of revolution; but that it is subject to disturbance by the three other giant planets, so that it needs a long series of observations to deduce the correct value; he says that Wolf gave too much weight to the rough observations of the eighteenth century, which were made before the sunspot cycle was recognised. It is well to point out, however, that confirmation of the 11·2-year period has been obtained from ancient Chinese observations of sunspots, also by study of the annual rings in old trees; Mr. Luby's period should therefore be received with some caution. As a check on his theory he notes that the present cycle should be an abnormally long one, lasting until 1936. He further suggests that the variation of solar rotation with latitude may also be due to planetary action, comparing the similar behaviour of Jupiter and Saturn.

Mention may also be made of Prof. Dinsmore Alter's work, on the lines laid down by Prof. E. W. Brown, of which a description was given in the *Journal* of the British Astronomical Association for last January. This ascribes the principal term in spot-variation to the combined action of Jupiter and Saturn, but recognises the action of the inner planets in producing variations of shorter period.

Research Items.

Sumerian Copper.—Further analyses of samples of prehistoric and early copper have been made on behalf of the British Association's Committee on Sumerian copper, the report of which was presented at the Association's meeting at Bristol. The number of specimens containing nickel is again to be noted, though no further light is yet thrown upon the sources of Sumerian copper. Specimens from Mohenjo-Daro numbering sixty-four were examined. Most were of copper, showing no traces of nickel, but twenty contained appreciable quantities, the highest being 1·49 per cent and the usual 0·3 per cent, this proportion being similar to that found in specimens from Mesopotamia. Nine specimens were of bronze, the tin ranging from 5·6 to 19·1 per cent. The specimens from the 1927 excavations were richer in nickel than those found in 1926. Specimens from the grave of Queen Shub-ad at Ur contained 0·51 per cent of nickel, while six bronzes from Kish (1928) showed 0·006 to 0·21 per cent with tin from 5 to 15 per cent. Mr. Woolley provided specimens from last year's excavations at Ur of First Dynasty date which showed nickel ranging from 0·165 to 0·46 per cent, while of five further samples from the British Museum two only showed nickel in appreciable quantities—0·84 and 1·61 per cent. The spearhead from the stratum immediately above the flood level, held to be the earliest metal object so far found, proved to be of copper with no more than traces of foreign material. Twenty specimens from Makran furnished by Sir Aurel Stein, in which tin ranged from 0 to 27 per cent, contained no nickel or only traces, except in one specimen, which contained no less than 1·27 per cent. In view of the suggested connexion between South African and Sumerian copper, a number of specimens from South Africa were examined but yielded no support to this theory, and an examination of Chinese bronzes ranging in date from the Chow to the T'ang period also demonstrated that their material appeared to be derived from entirely different sources from that of Sumeria.

Ancestor Cult in Ancient Egypt.—Mr. G. D. Hornblower, in *Ancient Egypt* for 1930, pt. 1, has a further note on ancestor worship in ancient Egypt. In his previous communication Sir Flinders Petrie's identification of the *ka* as an ancestor's spirit was confirmed and amplified. When Egyptian civilisation developed, the ancestor cult took on a form which obscured the essential principle. The cult originated in fear of the dead generally, who if neglected led a miserable existence, for which they might exact vengeance from the living. From this it was only a step to the loving care of the family for the spirits of the forefathers. In Egypt it was the sons, and especially the eldest son, who were responsible for carrying out the periodical funerary rites; and offspring were greatly desired to ensure the continuance of the funerary offices. The connexion was very close, and a son on receiving an injury would call on one or both of his parents for help. A dead husband or dead wife was addressed in the same way. Ancestor cult eventually culminated in the king, as the son of the strongest and greatest of the ancestors and the source of fertility. The king himself became a god. Thus, when in the sixth Dynasty the king assumed the title "Son of the Sun," it was with the political object of extending to the new sun worship the popularity of the earlier cult of the great ancestor Osiris, while by a compromise it was conceived that the king had two fathers, the sun and Osiris.

African Fresh-water Fishes.—Mr. Henry W. Fowler ("The Fresh-water Fishes obtained by the Gray African Expedition 1929." With Notes on Other Species in the Academy of Natural Sciences of Philadelphia. Vol. 82, 1930), in continuation of his studies of fishes from the Academy collections, describes a very interesting series obtained by Mr. Prentiss N. Gray on his recent expedition to equatorial Africa. Mr. Gray was accompanied on the expedition by Mr. W. W. Bowen representing the Academy as field collector, and valuable fishes were secured of twenty-five species, twelve of which are new to science. These belong to the Characidæ, Cyprinidæ, Clariidæ, Pœciliidæ, Anabantidæ, and Cichlidæ. There are detailed descriptions and good text figures, in many cases showing striking variations in marking. Besides Gray's fishes, other African fresh-water fishes from the Academy Collection are also described, including those from Lake Rudolph, collected by Dr. A. Donaldson Smith, and from Angola and Chilosngo, chiefly in the Quanza basin, purchased from Dr. W. J. Ansorge. Amongst these are two species of Polypterus, *P. bichei* and *P. senegallus*, in both of which variation of the head scales is shown.

Diurnal Migration of Plankton in Japanese Lakes.—Dr. Kenzo Kikuchi in his paper "A Comparison of the Diurnal Migration of Plankton in Eight Japanese Lakes" (*Memoirs of the College of Science*, Kyoto Imperial University, Series B, Vol. 5, No. 1, Article 3, 1930) records the results of his investigations in six freshwater lakes, one brackish and one of sea-water, the last closely connected with the Japan Sea by means of a small canal. With very few exceptions there is a distinct diurnal migration on the part of the plankton, and this is of several types, but the type is not constant for the species in all the lakes, the vertical distribution of the plankton in the daytime being presumably affected by the turbidity of the water. In a few cases temperature seems to determine the upper limit of both the diurnal vertical distribution and the nocturnal ascent. The upward movement of Crustacea takes place when the intensity of sunlight is changed. It is found that the younger forms of *Diaptomus pacificus* and *D. japonicus* are distributed nearer the surface than the old animals in the daytime and also they appear on the surface earlier in the evening, whilst the reverse is true in the order of leaving the surface in the morning. The nauplii of *Diaptomus* and *Bosminopsis* in Lake Kizaki have three maxima on the surface, in the evening when the sun sinks, after sunset, and at dawn. Other species have two maxima or one only. *Sagitta* and certain Crustacea are most abundant near the surface a few hours after sunset. Tables are given of the physical features of the lakes, the temperature, oxygen content, and hydrogen ion concentration, and in two cases the chlorine and hydrogen sulphide, taken on the same day as the plankton catches, also of the diurnal changes in the number of individuals and vertical distribution in the various planktonic species in the different lakes.

Origin of Nepheline-Syenite.—The nepheline-syenite gneisses and associated rocks of Dungannan Township, Ontario, are shown by F. F. Osborne to have had a complex origin; in part due to consolidation of magmas; in part to *lit-par-lit* injection; and in part to metasomatism (*Am. Jour. Sci.*, July, 1930). The sequence of differentiation in the granite and nepheline-syenite pegmatite dykes shows a remarkable parallelism. The evidence suggests that the parent magma of the nepheline-bearing rocks did not have the high content of volatile materials that has been claimed by some petrologists as a necessary factor in the genesis of such rocks. It is suggested that during the

formation of schists there is an elimination of the constituents that do not form foliated minerals, and that some of these constituents are those in which nepheline-syenite is rich. If they could reach a magma, they would necessarily modify its composition in the required direction. A similar suggestion for the origin of the spilitic suite of albite-rich rocks has been offered by Holmes (*Geol. Mag.*, p. 277, 1927). Both are supported by the work of Cooke on the constituents eliminated during thermodynamic metamorphism (*Museum Bull.* 46, Geol. Surv. Canada, p. 22, 1927).

The Disappearance of the Huronian.—Under this title T. T. Quirke and W. H. Collins describe the results of an investigation to ascertain what became of the Huronian formations of the Pre-Cambrian of Canada east of the line north-eastward from Killarney (Georgian Bay, Lake Huron) against which they seem to end (*Mem.* 160, Geol. Surv. Canada, 1930). They find that vestiges of the Huronian, highly metamorphosed and merging into gneisses of igneous aspect, do occur east of the line. The gneisses graduate in turn into massive granite from which it is not practicable to separate them. The authors suggest that the granite is mainly derived from parts of the transformed Huronian sediments which became liquid, while the gneisses were produced without reaching the fluid state. Structural considerations indicate that some of the belts north-west of the line were once buried about six miles and that the country to the south-east represents a still deeper section of the earth's crust, probably one of the deepest to be seen anywhere on the earth's surface. The gneisses and granites are called Killarnean. Sills and dykes of probably Keweenawan diabase (quartz-dolerite) preceded the intrusion of the Killarnean batholiths, and scattered dykes of fresh olivine-diabase followed. These facts show that the problems of the correlation and succession of the Canadian Pre-Cambrian are still very far from being solved.

Carthaginian Lenses.—The July issue of the *British Journal of Physiological Optics* contains a communication from Mr. H. L. Taylor on "The Origin and Development of Lenses in Ancient Times", which ascribes the development of the lens to the Cretans of 1800 B.C. His examination of the contents of museums of the eastern Mediterranean has led him to the conclusion that ivory and steatite, the materials used for beads prior to 2000 B.C., were replaced at a later period by rock crystal, onyx, agate, and cornelian. The discovery of the magnification produced by a bead of rock crystal led to the production of lens-shaped beads, and eventually of lenses such as those of the "royal gaming board" found in the palace at Cnossus and to the perfect lenses, found also at Cnossus and at Mount Ida, now in the museum at Candia. They are all plano-convex with powers between 5 and 8 diopters. The Phœnicians appear to have carried such lenses to the mainland, to Troy, Tyre, Nineveh, and Britain. At Carthage five glass lenses have been unearthed at the ancient necropolis, two of them, of power 5·5 diopters, in the sarcophagus of a prominent individual, who it is presumed suffered from presbyopia and wished to protect himself against this disability in his next existence.

Iridescent Colours.—In a paper in the August issue of the *Proceedings of the Royal Society*, Lord Rayleigh, after describing in some detail his experiments on the origin of the iridescent colours of birds and insects (see NATURE, vol. 125, pp. 211 and 474), discusses the action of light and of chlorine on these. The phenomena are complex, and perhaps the only generalisation that can be made is that stability of a colour under the chemical action of chlorine is a proof that no pigment is involved. The colours of the moth *Urania ripheus*, of the *Morpho* butterflies, and of metallic beetles survive such treatment, and there is much in favour of regarding these as interference colours. In other instances, such as that of the peacock's feather, where there is definite evidence that the colour is a structure effect but it is nevertheless affected by light, the conclusion reached is that the action of the latter probably consists in a photochemical destruction of the materials going to build up the structure. In another case, faded and unfaded parts of a *Morpho* wing were exposed to ultraviolet light, and it was found that the latter fluoresced, whereas the former did not; it seems likely that what had been destroyed in fading was some fluorescent body, itself colourless, which was built up into the colour-producing structure. A number of the properties of the peacock feather still remain to be explained.

Polar Properties of Ice Crystals.—In spite of its importance, there is still little general agreement on the crystallography of ice, largely because of the difficulty experienced in producing authentic single crystals. Prof. J. M. Adams, in some work described in the *Proceedings of the Royal Society* for August on crystals of microscopic dimensions, has obtained evidence that they are polar. When these were observed in an atmosphere favourable to their disintegration, individuals were occasionally found which, although possessing the simple external form of a short right hexagonal prism terminated by basal planes, nevertheless developed a pit at one end only of a certain axis (the *C* axis). In addition, two other types of disintegration were found with crystals of the same external form, one characterised by a pit at each end of this axis, and the other by a cavity at the middle, these being explicable as due to the two possible modes of twinning on the basal plane. Prof. Adams points out that there is further evidence for polarity in the form of certain rod-like snowflakes which appear to be pointed only at one end, whilst others, terminated at both ends by basal planes, look as if they have grown by the union of two of the former, point to point, and ascribes the polarity tentatively to an asymmetric location of hydrogen ions in a non-polar oxygen lattice.

Wave-Length of Hydrogen Atoms.—Although the wave-properties of electrons are now so well established that a 'camera' has been described for the application of electron diffraction to the investigation of structure (Prof. G. P. Thomson, August issue of the *Proceedings of the Royal Society*), very few experiments have been performed which show the undulatory nature of atoms or ions. The fact that the proton and electron of a moving hydrogen atom are together equivalent to a wave is, however, demonstrated by an investigation of the reflection of atomic hydrogen by lithium fluoride, described by T. H. Johnson in the issue of the *Journal of the Franklin Institute* for August. The hydrogen atoms were generated in a discharge tube, and after passing through a collimating system, were reflected from the crystal on to a target coated with white molybdenum oxide (MoO_3). This is reduced to a blue lower oxide where the atoms are incident, and so gives a permanent record which can be examined visually or photographed. So far only first order diffraction patterns have been obtained, with rather poor definition, but the wave-length of the atoms calculated from these is in accord with theory. Lithium fluoride is of special value for this work because it appears to retain any hydrogen atoms

which are not immediately reflected for a sufficient length of time for them to recombine to molecules, which do not then affect the target.

Alkali Photoelectric Cells.—The second July number of the *Physical Review* contains a paper by A. R. Olpin, of the Bell Telephone Laboratories, on the properties of photoelectric cells in which the alkali cathode has been coated with a film of a simple dielectric or an organic dye. Most of the substances studied have been found to increase considerably the sensitiveness of the cell to red and infra-red light, their action being accompanied by the appearance of a new maximum in the spectral response curve for the composite surface, to the long wave-length side of the single important maximum in the curve for an untreated surface. The frequency difference between the maxima is often about the same as that of the $1 \cdot 5\ \mu$ infra-red vibration of the oxygen–hydrogen, carbon–hydrogen, and nitrogen-hydrogen linkages, and it is suggested that there is a real connexion between this vibration-rotation frequency of the molecules and the changes in the properties of the surfaces. One important fact which emerges incidentally from this investigation is that many of the substances used to sensitise photographic plates also increase the electron current of a photoelectric cell, and, at least in some instances, affect primarily the same spectral regions. Einstein's equation for the maximum energy of emission of photoelectrons has been found to be valid for composite surfaces exposed to near infra-red radiation.

Transmission of Short-Wave Beams.—If the wavelength of a radio beam is less than about ten metres, experiments have shown that it will act in a very similar way to a light beam. These beams follow the inverse square law and obey the ordinary laws of refraction. In addition, obstacles of every kind appear to produce shadows. In a paper in the *Wireless World* for July 23, Dr. F. Noack describes experiments on the transmission and reception of these beams recently carried out in Germany. Messrs. C. Lorenz, of Berlin, in conjunction with Prof. Esau, of the University of Jena, have made experiments with a transmitter placed on the peak of the Brocken, in the Harz Mountains, at a height of 1140 metres. It was found that reception was best north-east of the Brocken, where the country is more or less flat and from whence the peak can always be seen. According to theory, the range would be about 110 kilometres, the distance of the visible horizon. At first the transmitter was erected at ground level on the Brocken, and it was found that the range varied between 76 to 100 metres. It was noticed that all over the range the signal strength was practically constant. Beyond this range it decreased with extraordinary rapidity, the width of the region over which this rapid decline took place being about 10 kilometres. It seems probable that in this region reception is no longer carried out by the aid of direct radiation, but is due to indirect refracted rays. It seems highly probable that the range of reception depends mainly on the distance of the horizon from the transmitter. Further experiments at a height of 500 metres, the transmitter being placed on a tower 16 metres high so as to cut out possible 'earth' effects, confirm this conclusion.

Indium.—The element indium, although widely distributed, occurs only in very small quantities and it is usually recovered from zinc blendes and flue dusts. In the *Chemical News* for July 18, Dr. G. Druce describes the preparation of indium sulphide from the black residue left after generating hydrogen sulphide from commercial ferrous sulphide and sulphuric acid. About half a gram of the element was obtained from about 150 lb. of the commercial iron sulphide.

The Geber Problem.—The question of the authorship of the Latin treatises ascribed to Geber and their relation to the Arabic chemical works of Jabir ibn Hayyan has been somewhat complicated by a discussion as to the authenticity of the latter. In a note in *Forschungen und Fortschritte*, July 10, Prof. Ruska announces the results of an investigation of some hitherto unknown writings of Jabir published by Dr. Holmyard in 1928. He concludes that the whole system of Jabir's writings are of Ismaelite origin.

Ignition of Carbon Monoxide.—A criticism of the work of Smithells, Whitaker, and Holmes on the above subject, reference to which was made in NATURE of April 5, p. 545, has been published by Bradford and Finch in the July number of the *Journal of the Chemical Society*. The authors describe experiments which lead them to consider that the experiments of Smithells, Whitaker, and Holmes were vitiated by the circumstance that the dielectric strength of the mixtures of carbonic oxide detonating gas with water vapour and with hydrogen were different. The conclusion of the previous experimenters, that hydrogen is more effective than water vapour in conferring ignitibility, is considered to be valid.

Adsorption by Silica Gel.—In the July number of the *Journal of the Chemical Society*, D. C. Jones and L. Outridge describe experiments on the adsorption by silica gel in the system *n*-butyl alcohol and benzene. Measurements on the adsorption both from the liquid and vapour phases were made, and the difference between the true adsorption as defined by Williams and that given by the equation of Ostwald and Izaguirre is attributed to capillary adsorption. The concentration of the solution thus adsorbed is shown to be equal to that of the equilibrium solution, in agreement with theory. Success in the measurements was possible owing to the use of a new method of analysis devised by D. C. Jones, which could be used with both very dilute and very concentrated solutions. The main theoretical point of interest of the paper is probably the use of the assumption that a certain amount of internal gel solution, varying considerably with the equilibrium concentration, is adsorbed not by the solid but owing to the liquid capillary forces, and in experiments where the adsorbent is immersed in the solution, or where the adsorption is from saturated mixed vapours, this portion will have the same concentration as the equilibrium solution.

Complex Soil Colloid.—Most of the information at present available concerning the colloidal complexes existing in the soil has been derived from consideration of the analogies in behaviour which such complexes exhibit when compared with similar complexes prepared by synthetic methods. In the *Rendiconti* of the *Reale Istituto Lombardo* for the present year (Parts 2-5), Dr. C. Antoniani describes a soil colloid containing 93 per cent of organic matter which he has succeeded in separating directly from soil. This substance maintains a constant composition, even after dialysis, and is regarded as homogeneous. In an acid medium it coagulates when the *p*H value is equal to or less than 6, whilst peptonisation occurs for values below 8; the isoelectric zone is included between these limits. The complex is composed of three distinct individual colloids of humic, silicic, and ferric character, the last being electropositive and protected. The protective influence is exerted by both the electronegative constituents, but mainly by the humic colloid.

Soils and Fertilisers in South Africa.*

By Sir FREDERICK KEEBLE, C.B.E., F.R.S.

THE problems of South African agriculture which await solution fall into two groups—those of arable and those of grassland. Of the two, the problems of grassland are potentially of greater importance.

GRASSLAND.

The grasslands of South Africa are poor and barren. Over vast areas the scant herbage serves scarcely to cover the ground even during the growing season. It turns brown and grows yet scarcer during the dry season. There are green hills in Natal and green pastures, and even in regions of low rainfall after summer showers the brown herbage grows green again. There are large areas of grassland in which the spring herbage is luxuriant and nutritious, but as spring advances the feeding value of the grass declines and cattle have often to submit and succumb to conditions of starvation.

It seems to be universally assumed that this state of affairs is due to lack of water and that it can best be remedied by introducing from other countries grasses of greater powers of resistance to drought. Much work of great interest along these lines, both on irrigated and non-irrigated land, has been done in South Africa, particularly by Dr. Pole-Evans at Pretoria. He has shown that it is possible to establish many grasses from other parts of the world and to obtain large amounts of food for stock from them. But the suggestion which has now to be made casts doubt upon this method as being the most important means of rejuvenating the pastures of South Africa. This suggestion is that many of the troubles attributed to drought are more properly to be ascribed to mineral deficiency. The hunger of the soil for phosphates is only one symptom, albeit a most important symptom, of these deficiencies. The land, or much of it, also lacks lime, and although the lack is well known, little is being done to remedy it. Yet lack of lime may prove to be a limiting factor of yield on both arable and grassland. Many officials maintain that the addition of lime depresses yield, and fail to consider that this in itself may be a passing symptom of a deep-seated trouble and want. It is encouraging therefore to report that both in Natal (Cedara) and in Rhodesia (Salisbury) experiments are now being carried out which point to benefits from liming.

With an insufficiency of lime and phosphates in the soils the herbage must perforce be deficient in these essential materials; the yellow or pale green colour of the grass betokens that it lacks nitrogen: and it is certain that there are also deficiencies in potash. What other deficiencies there are of other more obscure elements which may prove to be important only further research will show.

It is suggested that all these deficiencies have been brought about by simple cosmic processes.

South Africa is the stem of a funnel, the mouth of which is the equator. Of all that teeming life bred in the warmth and moisture of the tropics there must from time to time, as bees swarm, have migrated hordes of all kinds of animals. Debarred by the desert from invading the north, these migrant hordes have gone ever southward. Sometimes the grasslands which these migrants invaded were lush with spring grass and sufficed to feed the beasts; but at other times when the sun was fierce in summer and the growth of grass stood still, there was lack of herbage. Thus pushed by hunger the herbivora grazed the pasture bare to the bone. The grass over-grazed became worn and thin. Like a garment too much used, the herbage became rent, and through the rents rains, often of torrential violence, pierced and swept away the soil, aggravating the effects of over-grazing. So the vicious circle was completed and remains complete to the constant impoverishment of South African soils.

Any traveller in the Union may see the rivers leap to life in the rains which attack the earth, carve it out and bear it away, and run red with the soil washed from the land. He may likewise see in the veldt-burning practised by farmers yet another aid to soil impoverishment: for though burning brings young and sweet and early grass, the partial sterilisation of the soil which it produces releases the little store of hardly won organic nitrogen which is absorbed greedily by the young grass in the flush of its spring growth. The soil is soon depleted, so that long before drought imposes its veto, growth wanes and the veldt becomes brown and bare and barren. Flocks and herds are decimated, and the patient farmer praying for rain fails to realise that he himself offered them as a burnt-offering to the god of ignorance.

Under these conditions of over-grazing and erosion an age-long struggle for existence must have waged among the plants of South African grassland, and the struggle must have been of ever-increasing intensity as the soil became more and more depleted of its mineral contents and its nitrogen compounds. In this struggle those grassland plants with larger requirements of minerals and of nitrogen were the first to succumb. They ceased to be members of the grassland community but, retiring from the unequal struggle, continue to survive here and there in those favoured mineral oases wherein their larger mode of life finds satisfaction. The struggle is still going on, and now only the most niggardly of the plants, mean in what they get and what they give, survive. Except for a brief period in the flush of spring they yield but little sustenance to the animals which graze upon them.

If this picture of the evolution of the grassland of South Africa be true, conclusions of fundamental importance follow. The first of these conclusions is that the restoration of South African pastures is possible. The second conclusion is that the way of improvement lies in the restoration to the soil of conditions under which plants of larger requirements and higher nutritive value may live. The third conclusion is that the picture of the decadence of grassland in South Africa, although more vivid, is none the less identical with the, albeit more drab, picture presented by the world as a whole. The factor which has determined the trend of evolution in this as well as in earlier geological epochs is the decreasing supply of minerals stored in the grasslands and arable fields of the world.

Deficiency of nutritiveness of the plants of arable crops means deficiency of nutrition in man and beast, which in turn means disease, and it may be that the wealth of animal diseases which Africa possesses is but another symptom of the gradually lowered vitality of living things due to gradual decrease in the supply of essential minerals.

If this be true, then in grassland management with its insistence on the restoration of minerals there are means of arresting the downward trend of evolution, or at least of slowing down the rate at which nitrogen

* From a paper read before Section M (Agriculture) of the British Association at Bristol on Sept. 5.

and phosphorus escape, the one into space, the other into the abysms of the ocean.

Whether these large conjectures prove true or no, the first two conclusions require brief consideration. If it be true that a restoration of minerals to the soil brings about a return of plants of good grazing value, we shall have a most important vindication of intensive grassland management. For the general principle underlying the intensive management of grassland is that conditions may be provided wherein more nutritive native and introduced plants will flourish. That it will prove possible to transform the grassland of South Africa is rendered probable by the remarkable results which Mr. T. D. Hall's small scale experiments on grassland in different parts of South Africa have already achieved.

These experiments show:

(1) That grassland in South Africa responds in an almost magical way to nitrogen.

(2) That the relation between nitrogen and phosphates which obtains in grassland is the reciprocal of that which obtains on arable land. Though a dressing of phosphates adds but little growth to that produced by a single dressing of nitrogen, a dressing of phosphates added to a double dressing of nitrogen brings about a marked increase. The explanation would appear to be that the grassland plants surviving to-day are able to extract even from the impoverished soil just enough phosphates to live on; but in that grassland there is not enough nitrogen to go round, and so growth languishes until additional nitrogen is supplied. Addition of more nitrogen produces little effect. Addition of more phosphates as well as more nitrogen gives rise to a further increase in growth.

(3) The treatment of grass with a complete fertiliser together with lime gives the largest response.

These experiments suggest the conclusion that a brilliant future awaits South African grassland. It is even safer to conclude from them that our knowledge of the proper fertiliser treatment of grassland is only just emerging from the empirical into the scientific stage, and that the investigation of the nitrogen-phosphate balance with potash in attendance will lead to the discovery that grass can be made far more productive than is at present supposed.

The opinion that grass will play an important part in the future of South African agriculture is reinforced when South African rainfall is considered. Much of South Africa is a land of summer rainfall. Grass is the opportunist among plants; it grows during growing weather and dies down when conditions are unfavourable to growth. A drought may cut off an arable crop in its prime, but it can rarely do more than check the growth of grass. Experiments now being conducted in Natal, at the Cedara School of Agriculture, lend confirmation to the view that grassland in South Africa will respond to intensive management no less readily than the grassland in Great Britain. Mr. R. A. Fisher's experiments show that even a grass (*Paspalum* sp.) reputed by farmers to be of low grazing value, responds to fertilisers so remarkably as to produce enough food during the grazing season to enable one cow to yield 1000 gallons of milk.

One more suggestion may be made with respect to nitrogen on grassland. Owing to the intensity of the struggle for existence, grassland plants must always be hungry for nitrogen. Such nitrogen as grassland contains, and for which the plants have perforce to scramble, is derived from the breaking down of organic nitrogen compounds. The breaking down proceeds by orderly stages until compounds of ammonium are formed. The nitrifying bacteria then convert the ammonia first into nitrites and then into nitrates. It is usually believed that all plants of grassland, hungry as they are for nitrogen, wait passively until nitrate is formed before they attempt to supply their wants. It would seem more likely, however, that with capacities sharpened by the struggle, there would emerge from among some of the grasses the capacity to absorb nitrogen in the form of ammonia, or even in organic form, and such plants would be victorious in the struggle for existence. It may therefore be predicted that amongst grassland plants, some at all events may be found which possess the power of obtaining nitrogen in the form of ammonia, and it may prove that the grass family is distinguished from other plants by this capacity.

The dicotyledons, including the common weeds of pastures, can obtain nitrogen only in the form of nitrates, and to them ammonium compounds are poison. But the grass plants are able to utilise and thrive on the nitrogen obtained in the form of ammonia. Two facts support these suggestions. The first is that sulphate of ammonia and ammonium phosphates have a lethal effect upon the common weeds of grassland; the second, that sulphate of ammonia is at least the equal of nitrate nitrogen in calling forth the growth of grassland in spring. This equality is difficult to explain if the common view be accepted that before ammonia can be utilised by the plants it must first be converted into nitrates.

The power of sulphate of ammonia to evoke early growth of grass would be self-evident were it to be proved that ammonium compounds are the proper nitrogenous food for grass, and, needless to say, such proof should be of great value. Of no less value should be the proof, if it can be obtained, that ammonium phosphate is the right fertiliser to use on a plant which responds markedly to a proper balance of nitrogenous and phosphatic fertilisers.

ARABLE LAND.

The arable crops of South Africa are poor. The yield of maize in the Union is on the average three bags to the acre, that is, about one-third of a crop even when measured by American standards. Poor cultivation is in part responsible for low yields, far more so indeed than seems to be realised in South Africa. Other limiting factors are water and phosphatic deficiency, and it is a general obsession in South Africa that most of the agricultural troubles from which that country suffers are due to lack of water. Science should aid effectively in curing this obsession. It has already shown that in spite of low rainfall, crops can be produced if the deficiency of the soil in phosphates be made good. But even after applications of phosphates the crop remains small, and the expert attributes the low yield to insufficiency of water. In this he is partly, albeit only partly, right. When he adds nitrogen on the top of his phosphates the result is often disappointing, and he draws the conclusion that nitrogen, by encouraging the growth of leaf and stem and thereby increasing the loss of water from the plant by transpiration, does more harm than good by making the limited amount of water in the soil still more insufficient. For this reason the expert and the farmer avoid using nitrogen. Sometimes an additional reason is advanced; namely, that nitrification goes on so quickly in South African soils that there will always be enough nitrogen available when the plant needs it.

The latter explanation may be considered briefly and dismissed. South African soils are desperately poor in organic matter. Organic matter is the sole source of supply of natural nitrogen. If the source

of supply of natural nitrogen is almost non-existent, to believe that nitrification can supply enough nitrogen to the plants is to believe in the making of bricks without straw; albeit that it is possible to hold, as has been suggested, that the plant residues in the soil supply just enough material to permit of an amount of nitrogen fixation sufficient, and no more than sufficient, to make good the annual loss through nitrification.

The extreme poverty of South African soils in humus and the essential part which organic matter plays in the feeding of crops are facts which those interested in the use of fertilisers must take into careful consideration. Observations in South Africa have led me to propound some ideas which may throw light upon the rôle which organic matter plays in the soil. Hitherto it has been believed that the chief virtue of organic matter, apart from its physical effect on the soil, lies in the nitrogen which it supplies. Experiments made in South Africa on irrigated land are claimed by their authors to show that, whereas the addition of inorganic nitrogen produced no increase in crops, the addition of even so small an amount as 1 ton per acre of Kraal manure brings about marked crop increase. It is difficult, although perhaps not impossible, to believe that a small quantity of nitrogen in organic form is more beneficial to plants than a larger quantity of inorganic nitrogen. It is more reasonable to seek the benefit of the Kraal manure in the carbon which it contains, and it may be conjectured that the chief chemical rôle of organic matter is to supply carbon for the soil bacteria, and particularly for those soil bacteria which are engaged in nitrogen fixation. This consideration suggests a line of research of practical importance. If carbon in organic form be proved to play such an important part in enhancing soil fertility, it may become necessary to use as a 'filler' in the manufacture of complete fertilisers some cheap waste product rich in organic carbon. There are expert growers, some of them among the best in the world, who act empirically as though they held this view and use always large amounts of organic matter together with artificials in order to produce large crops of fruit and vegetables.

Considerations of the bacterial changes in the soil lead to yet a further suggestion; the wattle growers in Natal have proved that phosphates give a much larger growth of the tree than is obtained without their use. Now in a fairly wide excursion throughout South Africa, one of the few signs of nitrogen plenty was shown in the green-black colour of the leaves of wattles treated with phosphates. The dark colour suggests that the wattles have received plenty of nitrogen. But the soil is poor in nitrogen. Therefore the trees must have obtained it from the nitrogen-fixing nodule organism which infects the roots.

Inquiry showed that on the roots of the phosphate-treated trees the nodules are far larger than on the roots of trees without added phosphates. Phosphates are known to encourage nitrogen-fixing bacteria, but it is now suggested that these latter organisms are no less intimately connected with phosphates than they are with nitrogen; in other words, that they not only bring nitrogen from the air into organic combination, but also that they do the like for the phosphates of the soil. If so, these nitrogen-fixing soil bacteria are the foundation-stones of soil fertility and their prevalence is determined first by the supply of organic carbon in the soil, and secondly by the supply of phosphates.

In support of this suggestion it may be mentioned that the nodule-forming nitrogen-fixing organism of clover is said to possess the power (denied to other grassland plants) of obtaining its phosphates from insoluble sources — a belief which could be easily verified. If it be true, it should be possible to balance, as a juggler does balls, the clovers and grass constituents of a pasture by supplying phosphates now in soluble now in insoluble form. If this possibility were achieved it would have great practical value. All these things considered, it may prove that although South African soils are at present poor, their defects can be gradually remedied by the systematic use of fertilisers containing nitrogen and all the essential mineral elements as well as carbon compounds in a suitable form.

Another and extraordinary fact lends confidence to this prediction. Trees of many kinds and in the different States of the Union—Natal, Orange Free State, and Transvaal—grow with far greater vigour than they do in Europe. This fervour of growth is attributed in South Africa to water. It cannot be: for water could at best make the trees grow only as fast as they grow in Europe and not faster. Therefore among contributing causes to the vigour of growth not the least must be larger supplies of minerals. Unlike surface-rooting plants, trees can dive deep in the soil and from the deepest layers recover the phosphates which have vanished from the surface.

Lastly, there remains to consider the second of the two alternatives already mentioned in explanation of current failure of nitrogen to give increased crop production on land treated with phosphatic fertilisers; this suggestion may be stated thus. The amount of phosphates given to crops is 200 lb. to the acre —an extremely light dressing. The soils of South Africa are desperately hungry for phosphates. There is no reason to suppose that 200 lb. per acre satisfies their needs, especially for such a phosphate-greedy crop as maize.

Lack of phosphates may still be limiting crop production, and if so the addition of nitrogen would certainly do more harm than good. A double dressing of phosphates is known to give further increase of crop yields, but there is no reason why even a double dressing should completely make good phosphatic deficiency. There is evidence that 800 lb. or 1000 lb. to the morgen goes on increasing yields; and it is therefore suggested that the fundamental experiment is one in which a phosphate-needing plant (for example, maize) is grown in a series of soils which receive from 200 lb. to 1200 lb., or more, per acre together with a uniform light dressing of inorganic nitrogen, in order to ascertain whether when phosphate deficiency is completely remedied, nitrogen does not begin to come into beneficent operation.

With that experiment should be made an inquiry into the morphological effect of phosphates, that is to say, the effect of phosphates on modifying the relative growth of the root system and the shoot system. Phosphates are known to encourage root growth. It is suggested that with progressive increases in phosphates root growth may be more and more increased with the corresponding discouragement of stem growth. That would mean that the plant becomes both a more and more efficient collector and a greater and greater economiser of water. For with increased root more water is absorbed, and with reduced leaf and stem loss of water from the plant is reduced. If this proves indeed to be the case, then a changed technique might vindicate nitrogen as a crop producer in the dry soils of South Africa. The change would consist in regulating the amount of nitrogen in relation to the phosphates and in applying it as a top-dressing after development has proceeded to a certain extent, and not as at present with the seed. Along with this series of experiments there should be another which would analyse more

completely than has yet been done the well-established fact that fertilisers increase water economy in the growing plants. It has been shown in India and elsewhere that when fertilisers are supplied to plants economy in the production of dry matter is increased. But at the same time the total amount of dry matter may be so increased as to make more demands upon the soil water-supply than are made by the plant which receives no fertilisers. One of the most important problems before scientific agriculture must therefore be a working out of the most water-economising ration of artificials to be supplied to different kinds of plants.

There are also experiments to be made in discovering varieties of maize and corn which will respond to fertilisers more effectively than those now grown, and there are also other genetical experiments which need to be carried out designed to discover races with male inflorescences which will continue to produce pollen over a long period, so that even if drought comes there may still be some pollen left after rain has restored growth to the plant.

There are other experiments of no less essential importance in relation to liming - a practice which is neglected in South Africa—and there are yet others: to seek in carbon fixation carried on in uncropped soils the origin of the amazing renewal of fertility which fallowed fields display.

This sketch of the scientific problems which await solution shows incidentally how closely the future of the industry of agriculture depends upon the advances of pure science, and suggests how important it is for that industry both to encourage the investigations and to take part in them.

I found South Africa in large part barren land; if the ideas with which it has inspired me are true, they may yet make it fertile. I myself believe that a great future lies before that country, for I think that on those high uplands so near the skies and so richly irradiated by the sun the plants and the animals derive greater sustenance from the irradiated foods than do the animals of lower altitude and lesser suns. I believe, moreover, that in that great mineral deficiency which has been described lies the original source of all those troubles which South Africa endures. It is, I believe, defective nutrition that has brought in its train the many maladies which afflict man and beast. If so, when the grass is restored to its full vigour animals will renew their youth and defeat the attacks of now victorious parasitic pests. On those parts of South Africa from which those parasites are banished the trees grow stronger than they do elsewhere, the men and women are sturdier, and even the flowers are more exuberant and more substantial than they are when we grow them under our sadder skies.

Anthropology—Old and New.*

WHEN we look back to the times in which Dr. Beddoe lived and worked and note the doings of the men who were searching into the beginnings of the British people, we see that we owe more to him than to any other anthropologist of the Victorian epoch. It was he who laid our present knowledge upon a sure basis. He set out in his youth to find an answer to an age-old query: Of what race or races are we British?

Dr. Beddoe was born in Galton's 'brain-belt', which, passing from Liverpool to Swansea, includes the English counties bordering on Wales. Bristol is indebted to this belt for many of her most distinguished citizens. It gave her Dr. James Cowles Prichard, who made England famous in the annals of anthropology in the first half of the nineteenth century. This belt coincides with an old ethnological frontier across which Saxon and Celt have freely exchanged their heritage of blood; and it was their place of birth which turned the minds of Prichard and Beddoe to the problems of race.

Beddoe while still living in his father's house at Bewdley listened to discussions concerning the Celts, especially as regards their colouring. No one, he discovered, had made a census of the colouring of the people called Celts or of any other race of mankind. He determined to investigate the colouring of the British races by exact methods. He entered into a virgin field of investigation, and it was necessary for him to invent methods of making records of colour of hair, eyes, and complexion. He began his investigations at the age of twenty, and visited Ireland, Wales, the Highlands of Scotland, the Orkneys and Shetlands, and France in the pursuit of his investigation. The Crimean war, in which he served as a medical man, and a subsequent period of study at Vienna gave him the opportunity of observation in the Baltic, the Near East, Croatia, Styria, and Italy. When he settled down to practise in Bristol in 1857 there was no one in Europe had his exact knowledge of the western peoples. There was not a single year between 1857 and 1891, when he retired to Bradford-on-Avon, that Dr. Beddoe did not carry out an anthropological raid of some kind—on the Continent, or in Ireland, Wales, Scotland, or England.

There was another side to Dr. Beddoe's inquiries. There were many in Dr. Beddoe's day who feared that industrialism would ultimately undermine the health and strength of the people of England; but he was one of the few to pass from speculation to actual inquiry. So he set himself to measure height, weight, size of head, colour of hair and eyes, not only of every stratum of the population of Bristol, but also of the open-living inhabitants of surrounding counties. From his results there emerged a suspicion that city life was shortening stature and favouring the lighter rather than the darker haired types.

Beddoe was the first to ascertain how city life affects racial types. He found that far from the type becoming uniform under the influence of city life, there was a tendency to segregation of types: the racial traits which prevailed among business men were not those which marked the artisan. In the selection of their mates, the men of Bristol preferred blondes to 'reds' and 'blacks'. Disease and conditions of industrial life, on the other hand, favoured those who had a dark complexion rather than those who were fair-skinned. Emigration was selective; it tended to rob Bristol of its best. Beddoe perceived that the effects produced by city life on the body and mind of man presented problems which could be solved only by patient and careful inquiry. It is this side of Beddoe's pioneer labours which needs to be stressed. We cannot be comfortable concerning our future until we know what is happening to us. A city population cannot stand still. The medical officer keeps his finger on the pulse of public health; there should be an anthropologist to keep his finger on the pulse of type—physical and mental. Beddoe's work on the population of Bristol should find its logical outcome in the institution of a chair of physical anthropology in the University of Bristol.

Dr. Beddoe devoted the spare time of his manhood to amassing data concerning the colouring and other physical traits of the peoples of western Europe—

* Abstract of the Beddoe Memorial Lecture delivered by Sir Arthur Keith, on Sept. 5, in connexion with the Bristol meeting of the British Association.

particularly of the communities of the British Isles. What was the net result of all this labour? The gain was two coloured anthropological maps—one of the British Isles, another of Europe. It may be felt that Dr. Beddoe's 'unequalled perseverance' had a meagre reward. That is not the case; these two maps are the most valuable contribution ever made to our knowledge of the history of the inhabitants of western Europe. Dr. Beddoe was born in a period when men believed that all that can be really known about the history of our ancestors was in the works of ancient writers. Dr. Beddoe was the first to show us that our racial history is written in our hair, eyes, skin, skulls, faces, and temperaments.

It is the business of anthropology to gather from every source facts which throw light on the origin and nature of nationalities and races. Dr. Beddoe performed this service for Britain in a way that no one has done before or since. How do we treat men who render our country such a signal service? In 1885 Dr. Beddoe published his greatest book, "The Races of Britain". Into this book he compressed thirty-two years of devoted labour. Yet no one proclaimed then what the book was—and what it still remains: the greatest treasury of anthropological fact which has ever appeared in any language. How can amends best be made? Orthodox honours came his way but were not commensurate with his deserts. In what way can we honour his memory better than by seeking for the means to establish in the University of Bristol a chair of anthropology? Beddoe was the great amateur in his chosen subject. With the present century anthropology reached the stage in which professionalism became imperative. In order that a professional anthropologist may live, a university must provide him with a chair. In return he gives a service of knowledge to the university and to the community in which that university is situated. Dr. Beddoe's teaching and example are not dead, and there awaits the occupant of a chair of anthropology in the University of Bristol an infinite number of problems which need solution.

From 1810, when Dr. Prichard began practice, until Dr. Beddoe's death in 1911, Bristol was known throughout the learned capitals of Europe as a centre for the study of the human races. In Bristol the time is ripe—more than ripe—for the institution of a faculty of anthropology. No university, no city, no locality can rival Bristol in the opportunities it offers for the scientific study of mankind. Above all, the institution of a chair of anthropology in its University is an act of justice due to the memory of a great citizen—the late Dr. John Beddoe.

University and Educational Intelligence.

THE Worshipful Company of Woolmen has awarded a silver medal to Mr. F. F. Darling, of the University of Edinburgh, whose thesis on "Studies in the Biology of the Fleece of the Scottish Mountain Blackface Breed of Sheep" is considered as likely to prove basic to all future studies on both this particular breed of sheep and on other breeds in general. The Company has also awarded a silver medal to Mr. N. H. Chamberlain, of the University of Leeds, for a thesis upon "The Thermal Conductivity of Textile Materials and Fabrics". Certificates of merit have been awarded to Miss Emma Stott, of the University of Leeds, for "A Contribution to the Theory of Milling: a New Method of Measuring the Scaliness of Fibres", and to Mr. N. Cryer, of the University of Leeds, for a thesis on "Variation in Spindle Speed".

THE London County Council has again arranged courses of lectures for teachers, and a Handbook has been issued which includes synopses of the courses (County Hall, London, S.E.1). Last year the entries for these courses exceeded 14,000. Any person engaged in teaching in London, Croydon, Kent, Middlesex, or Essex is eligible for admission at fees which average less than 1s. a lecture, while other teachers are admitted at fees 50 per cent higher. The lectures undoubtedly form an important part of the educational system in London, for they bring teachers into touch with new developments in educational methods, and give them opportunities of hearing leading authorities in various branches of learning. Readers of NATURE will be interested in the following courses: Five special single geographical and travel lectures, by Mr. A. Victor Murray, Mr. J. A. Steers, Major R. W. G. Hingston, Dr. T. F. Chipp, and Dr. L. Dudley Stamp; and the courses on types of geographical regions (Dr. J. F. Unstead); geography in senior schools (Mr. R. H. Ducé); history of geographical discovery (Prof. E. G. R. Taylor); mathematics in senior schools (Sir Percy Nunn); practical mathematics in senior schools (Mr. J. A. Phillips); psychology of the junior pupil (Prof. Cyril Burt); fundamentals of psychology (Dr. J. G. Vance); vocational guidance (staff of the National Institute of Industrial Psychology); science teaching in senior schools (Mr. G. H. Leslie); physics in senior schools (Prof. C. R. Darling); biology in senior schools (Miss C. von Wyss). The attention which is being given to the needs of teachers taking up the new post-primary work is noteworthy. It is stated that the loan collection of lantern slides at the County Hall now exceeds one hundred thousand.

HIGHER education in the United States forms the subject of a symposium published in vol. 69, No. 5, of the *Proceedings of the American Philosophical Society*. This comprises an address by Abraham Flexner and papers by Frank Aydelotte and F. J. E. Woodbridge. The first surveys the conditions, actual and probable, of the advancement of knowledge (*a*) by individuals working independently, (*b*) through academies and associations of specialists, (*c*) through research institutions devoted to specific ends, (*d*) through foundations that award stipends for research, and (*e*) through universities. Under the headings (*a*), (*b*), and (*c*) the conditions are pronounced to be propitious. As regards (*d*), Dr. Flexner emphasises the increasing difficulties in the way of proper selection of stipend holders. He devotes the latter part of his address to a trenchant criticism of the "heterogeneous conglomeration of useful and useless, of important and trivial activities, now carried on under this term—university", which he likens to a metropolitan drug store. For the moment the trend in universities is away from what seems to him sound, natural, and ideal and towards what is unsound, unnatural, and unideal. The other two papers deal only with college administration. Both recognise the existence of the evils deplored in Dr. Flexner's address and offer constructive suggestions for combating them, the former by means of a tutorial system for students who have demonstrated their capacity to profit by it. This system has been in operation for some years at Dr. Aydelotte's own college, Swarthmore, with the happiest results. Dr. Woodbridge develops a plausible argument for scrapping half of the ordinary college curriculum, simplifying and strengthening the remainder for the explicit purpose of pre-professional training for the professional schools, and utilising the financial saving thus effected for expanding the calibre of the staff.

Historic Natural Events.

Sept. 14, 1716. Thames Dry.—After an excessive drought, which continued from February to the end of August, a strong west-south-west wind prevented the tide from coming in for 24 hours, so that there was only a narrow channel some 10 yards wide, and so shallow that thousands of persons passed across on foot, under the arches of London Bridge.

Sept. 14, 1899. Floods in Austria.—Heavy rains fell on Sept. 8–14. At Mühlau the fall on Sept. 12 was 11·3 in. in 24 hours, and the total for the six days exceeded 24 in. The Danube rose to a level nearly 25 feet above the low-water stage at Vienna and nearly twice this amount in some other localities. The floods, which were exceeded only by those of 1501, did great damage.

Sept. 15–17, 1929. Thunderstorm near Channel Islands.—A remarkably severe thunderstorm raged almost without cessation over a small area near Dinard and the Channel Islands from 6 P.M. on Sept. 15 to 4 P.M. on Sept. 17, accompanied by violent winds from the north-east. There was considerable damage both by lightning and flood; the power station at St. Brieux was put out of action, and at Dinard an Englishman was blinded. A bridge on the main Dinard-St. Lunaire road was swept away and a motor-car crossing at the time was washed out to sea. St. Lunaire was flooded to a depth of two feet and the streets torn up.

Sept. 16, 1363. Beginning of Severe Winter.—According to various old chronicles, a "very terrible" frost continued from the middle of September into April. Holinshed, quoting "Walsingham and other old writers", says Dec. 7–Mar. 19. In Paris the frost began on Dec. 6 and lasted 14 weeks. The Rhine was frozen from Jan. 5 to Mar. 17, and waggons were driven over the ice. In France the winter was very snowy.

Sept. 17, 1882. Great Comet.—On this day, the great comet, visible to the naked eye in full daylight, was followed telescopically right up to the edge of the sun by Mr. Finlay (the discoverer of the comet on Sept. 7) at the Cape of Good Hope Observatory. Even the nucleus was quite invisible, however, as the comet crossed before the sun's disc. At Melbourne the comet was watched with the unaided eye to within 4° of the sun. By Sept. 24, it was visible with a tail 15° long in the bright dawn. Success in photographing this comet and its background of stars at the Cape Observatory under the direction of Sir David Gill was an important factor in the inception in 1887 of the Astrographic Chart and Catalogue. The period of the comet is 761 years.

Sept. 18–19, 1926. Florida Hurricane.—Early on Sept. 18 the south-eastern coast of Florida from Miami to Palm Beach was struck by an intense hurricane, which on the previous day had ravaged the Turks and Caicos Islands. The centre, moving towards the west-north-west, passed almost over Miami, where the official barometer fell to 936 mb. (27·65 in.). During its approach the wind reached hurricane force (75 miles per hour and upwards) for nine hours, and the greatest velocity is estimated as 130 miles per hour. Then, as the centre passed over, there was a lull and large numbers of people, not realising that a second phase was coming, ventured out, to be caught when the wind rose again to hurricane force in the rear of the centre. The strength of the wind is shown by the nature of the damage; an 18-story skyscraper recently completed was twisted so badly that it had to be demolished, and another tall building was bent over twenty degrees from the vertical. Yachts and small ships were lifted bodily on to the land. After passing Miami the hurricane curved away to the north-west, striking the Gulf Coast between Mobile and Pensacola on Sept. 20 and dissipating over eastern Texas on Sept. 22. In Florida 327 persons were killed and more than 6000 injured, and the damage to property probably exceeded 100,000,000 dollars, and was greater than in any previous hurricane in the United States.

Sept. 19, 1387. End of Hot Summer.—The summer in Europe was extraordinarily dry and hot and was proverbial for centuries as "The Old Hot Summer". From Feb. 28 to Sept. 19 it rained only six times in Switzerland, and men waded across the Rhine at Cologne. The year was not especially dry in England.

Sept. 19, 1540. Drought.—After a calamitous year, fine weather and heat lasted from February until Sept. 19, during which interval scarcely any rain fell in Europe.

Sept. 20, 1909. Storm Wave through Yucatan Channel.—A tropical hurricane of great intensity and large extent passed through this Channel on Sept. 17 and struck the coast of Louisiana a short distance west of New Orleans on Sept. 20. A great storm wave swept inland, and the water, checked by the swamp forests and levees, reached a depth of 7-10 ft. over a large area to the right of the centre, including New Orleans. The damage to property caused by this storm exceeded six million dollars and 353 lives were lost.

Sept. 20, 1929. Hurricane in West Indies.—This disturbance was first reported about 300 miles north of Porto Rico on Sept. 20; at that time it was of moderate intensity, but by Sept. 24 it had reached hurricane force. It was, however, chiefly noteworthy for its abnormally slow rate of movement and aberrant track. From Sept. 24 to Sept. 28 it actually moved in a south-westerly direction across the Bahamas and through Florida Strait near Miami. At Nassau, Bahamas, on Sept. 25 a violent westerly gale caused a 'hurricane wave' which destroyed the sea wall and flooded the town, carrying away many houses. Many others were unroofed, stores, churches, and shipping were damaged, and many lives were lost. In Florida the damage was much less, and the centre was evidently decreasing rapidly in intensity, but at Miami there were a number of waterspouts and at Key Largo the wind velocity during gusts was estimated as 150 miles per hour. From Miami the centre moved very slowly north-westwards to Panama City near Pensacola, where a few wharves and stores were destroyed on Sept. 30.

Societies and Academies.

PARIS.

Academy of Sciences, July 21.—**G. Bigourdan**: The astronomical stations of Châtillon-sous-Bagneux.—**L. Blaringhem**: The heredity of the phases of flower opening in poppies.—**F. Mesnil**: The adaptation to man of the trypanosomes pathogenic to mammals. The author considers that it has been experimentally demonstrated that a trypanosome of animal origin, such as *Tr. brucei*, can adapt itself to man.—**M. Aubert** and **R Duchêne**: The propagation of combustion in carburetted mixtures.—**G. Bruhat** and **J. Terrien**: The comparative absorption of active and racemic acids in aqueous solution. Between the wave-lengths 2653 A. and 2400 A., if racemic acid absorbs light differently from solutions of the active acids, the deviations are always less than 4 or 5 per cent in one direction or the other, and the average of

the results shows that the absorptions are practically identical. These results confirm those deduced by Darmois from polarimetric measurements.—**Daniel Chalonge**: The mechanism of the continuous emission of the hydrogen molecule.—**H. Ollivier**: The thermal variation of the specific magnetic rotatory power in the case of cerium nitrate and nickel chloride.—**F. Joliot**: The determination of the period of radium-*C*′ by Jacobsen's method. Experiments with thorium-*C*′. —**Horia Hulubei**: The preparation of very pure hydrogen in notable quantities by means of an electrolytic osmoregulator with palladium. The palladium tube of an osmoregulator is saturated with hydrogen by electrolysis of phosphoric acid, the anode being arranged so that the palladium tube is not altered in shape. By afterwards heating this tube, relatively considerable quantities of hydrogen are introduced into the vacuous tube.—**Picon**: Rendering some salts of camphocarbonic acid soluble in organic solvents. Various camphocarbonates, rendered anhydrous by prolonged exposure in a good vacuum over phosphoric anhydride, were examined for their solubilities in organic solvents. Some of these (neodymium, cerium, bismuth, gold) are readily soluble in organic solvents, others (copper, calcium, zinc, lead) when anhydrous are practically insoluble. But boiling with benzene, with subsequent removal of all the benzene, renders these salts more or less soluble in organic solvents.—**Mlle. M. Montagne** and **B. Casteran**: The action of potassium hypobromite on some trisubstituted amides. The α-trisubstituted amides give good yields of iso-cyanates when submitted to the Hofmann reaction; subsequent treatment with hydrochloric acid gives the corresponding amines in quantitative yield.—**Jean Gubler**: The geological structure in central western Cambodia (Indo-China). **A. Marin, M. Blumenthal,** and **P. Fallot**: Stratigraphical comparisons between the western extremity of the Betic and Penibetic zones of Andalusia and the north of the Riffian arc.—**Louis Besson**: The daily variation of rain at Paris. A discussion of twenty years of observations made at the Observatory of Montsouris. The mean daily variation has two maxima and two minima, and this is due to two different causes, the daily convection currents and the nocturnal cooling.—**M.** and **Mme. H. Labrouste**: The relation between certain periodical components of the solar activity and the daily amplitude of the magnetic declination.—**Couvreur**: Preliminary note on the structure of the shells of Gastropods.—**Alb. J. J. Vandevelde** and **Alfr. Verbelen**: New biochemical researches on earth. The dye absorption method gives very variable results with the same earth, even with the same dye; results using methylene blue were the most concordant, but further study is necessary. The adsorptions of dye, peptone, and centrifuged milk were compared. The three methods gave roughly comparable results. **M.** and **Mme. A. Chauchard**: Researches on the relation between functional velocity and chronaxy.—**Raymond-Hamet**: The comparative physiological action of aspidospermine and quebrachine. In opposition to the usually accepted view, the alkaloids of *Aspidosperma Quebracho* must be classed in two different pharmacological groups. The experiments described show that the total alkaloids of this plant can act at once on the vagus nervous system and on the sympathetic nervous system. This suggests a new therapeutic application of these alkaloids.—**G. Belloc, R. Fabre,** and **H. Simonnet**: Contribution to the study of the biological activity of the sterols. Study of the plankton sterols. From two samples of plankton, taken at different periods of the year, the sterols were extracted and purified, care being taken to exclude the action of air and light so far as possible. These sterols were submitted to physical (absorption in the ultra-violet), chemical, and biological tests. One, collected in July, was biologically active; the other, collected in April, only acquired biological activity after irradiation. The biological activity of the plankton depends on several factors, the chief of which are light and the zoological nature.—**Mme. Y. Khouvine, E. Aubel,** and **L. Chevillard**: The activity of sodium fluoride towards the transformation of pyruvic acid into lactic acid.—**H. Colin** and **E. Guéguen**: The constitution of the sweet principle of *Rhodymenia palmata*. This is shown to be a monogalactoside of glycerol; the fresh alga may contain up to 5 per cent of this substance.—**M. Marcille**: The injection of formolated ether into the lymphatics of cancerous tumours. Injection of ether containing 0·5 per cent of formol is proposed, and one case in which it proved beneficial is described.

CAPE TOWN.

Royal Society of South Africa, June 18.—**H. H. Karny**: On the geographical distribution of the Indo-African and Mediterranean Gryllacoids. Seven subfamilies are considered, representing the forms occurring in the regions under consideration. In the case of the *Stenopelmatinæ* and *Anostostominæ* there is a discontinuous distribution. In the case of the other subfamilies, some forms are endemic in India, but all other forms occurring in India show relationships to those found farther east, where more species also occur.—**B. F. J. Schonland**: Thunderstorms and the penetrating radiation. An examination of the effect of thunderclouds upon the intensity of the penetrating radiation, using a new type of ionisation-electroscope, was made at Johannesburg, in the summer of 1929–1930. Overhead storms give rise to a reduction in intensity, amounting to so much as 40 per cent. No evidence could be obtained for the existence of beams of 'run-away' electrons below these clouds. The reduction effect indicates that the majority, if not all, of the ionising particles have energies less than 5×10^9 electron-volts.—**Enid Hogben**: Sex differences in serum calcium in different classes of vertebrates. In the rabbit, dogfish, and crawfish, the calcium content was higher in males than in females, but the difference was not statistically significant. In the fowl and toad, the calcium content was significantly higher in females. In the rabbit, fowl, and toad, magnesium determinations gave parallel results to those of calcium. In the crawfish the magnesium content of the serum was significantly higher in females. In the dogfish the magnesium content of the serum gave a wide range of values. This variability may be connected with the different stages of the reproductive cycle in the female.

MELBOURNE.

Royal Society of Victoria, July 10.—**T. Rayment**: New and remarkable bees. *Meroglossa miranda*, a West Australian species with maxillary palpi larger than the antennæ, was described. Also the first recorded female of *Neopasiphae mirabilis*, from the Best collection in the National Museum. Other descriptions include *Paracolletes maculata*, *Neoceratina rubinii*, *Trigona cockerelli*, and the allotypes of *Halictus demissus*. An emendation of *Melitribus* is given.—**C. J. Gabriel**: Catalogue of the land shells of Victoria. The records of previous authors are here brought up-to-date and a critical revision of the species made. Eight new species are described.—**W. J. Parr** and **A. C. Collins**: Notes on Australian and New Zealand Foraminifera. (1) The species of *Patellina* and *Patellinella*, with a description of a new genus, *Annulopatellina*. A trimorphic variety of *Patellina corrugata*

is recorded, resembling *P. advena* Cushman. A new species, ***Patellinella annectens***, is described. The new genus, ***Annulopatellina***, is founded on the genotype *A. annularis* (Parker and Jones).—**F. Chapman and Irene Crespin**: Rare foraminifera from deep borings in the Victorian Tertiaries. Six new species and a new variety are described.

Inventions and Unemployment.

FROM the days of the Luddite riots onwards men have felt vaguely that there is some kind of relation between inventions and unemployment. It is a little astonishing, therefore, that at a time when unemployment has become the most pressing of all social problems that that relation should be receiving so little attention from statesmen.

The only systematic attempt to study the economic effect of patents appears to have been that made twenty years ago by Mr. Ravenshear in his little book " The English Patent System ". Mr. Ravenshear regarded inventions as ranging between two extreme types, the originative, which creates new demands and so absorbs labour, and the intensive, which cheapens the production of known commodities and tends, subject to certain reservations, to create unemployment. Mr. Ravenshear concluded that the patent system acts selectively by fostering originative inventions to a greater extent than intensive inventions, the output of which is far less dependent on special encouragement of this kind. If his view be correct, the patent system, in so far as it is efficient, tends directly to promote the absorption of unemployed labour. But however that may be, it is certain that if British manufacturers are to compete successfully with foreign rivals, they must have the advantage of a constant succession of inventive improvements, and the present is not a time to tolerate delays or other defects due to parsimony in the administration of the system.

Early last year a number of questions were asked in the House of Commons with regard to the arrears of work which had accumulated at the Patent Office, and some disturbing facts were elicited. It was learned that inventors had to wait seven months before the Patent Office could begin to turn its attention to their applications for patents, that 8400 complete specifications were awaiting the first action of the examiners, that the amount of work to be done annually had increased by 27 per cent while the strength of the examining staff had decreased by 11 per cent, and that this economy, effected at the expense of efficiency, had enabled the Patent Office to hand over to the Treasury no less than £112,939 in one year. This state of things was generally felt to be a very serious one. It often happens that opportunities for exploiting an invention commercially occur but will not wait, and beyond question these opportunities for creating employment are sometimes lost and

often postponed because of the false economies which have been effected in the administration of the patent system of Great Britain.

It might have been supposed that when attention had been directed to this matter the Board of Trade would have dealt with the problem resolutely and effectively. Actually, however, it was content with some such makeshift provisions as would avert the crisis for the moment without in any sense curing the evil. To-day inventors are not conscious of any material improvement, and meanwhile, according to the report for 1929 of the Comptroller-General of Patents, the annual surplus of fees over expenditure has risen to £157,005.

Another instance of the casual attitude of officialdom towards patent matters is to be found in the treatment meted out to the technical staff at the Patent Office. Applicants for important patents are surprised to find, on visiting the examiner whose demands they are required to satisfy, that he works in an overcrowded and badly lighted room, that he and his contemporaries have served for perhaps twenty-five years without hope of promotion, and that the Comptroller and Assistant-Comptroller, who are responsible for a service on which enormous amounts of capital depend, receive (according to the Civil Estimates) emoluments which amount in all to £1686 and £1306 respectively. Scientific knowledge and ability is cheaply valued by the secretariat of the State. Scientific men are being definitely exploited in the interest of a parsimony which wears very awkwardly the disguise of economy.

Some time ago a departmental committee under Sir Charles Sargant was appointed by the Board of Trade to inquire into the demand which has arisen for a general revision of the patent laws. Departmental committees are sometimes appointed with a practical object, and sometimes for use as pigeon-holes. Is there on the Sargant Committee a majority of positive-minded men whose temperaments will lead them to seek for positive solutions of the problems presented to them? Or has the majority been selected from among men of negative temperament, who can be relied upon to make out "an overwhelming case for doing nothing"? Time alone can answer these questions, and until they have been answered no inference in either direction can be drawn from the appointment of the Sargant Committee.

The general attitude of *Messieurs les Ronds-de-Cuir* is indicated by a reply given on Mar. 5, 1929, to a question in the House of Commons with regard to the Patent Office financial surplus. The Board of Trade has retreated from the position taken up in 1891 by Sir Michael Hicks-Beach, who stated (July 14) that "he did not think that the country ought to look to the Patent Office as a permanent source of income". To-day the Board relies on the fact that patent fees are paid by instalments, and that the first instalment, without subsequent renewal fees, does not pay in full for the administrative cost of grant. "Obviously," said its president, "the applicant for a patent who is charged a fee which does not actually cover the amount of work done is not being charged too much."

Thus, the Board of Trade has entirely misconceived the purpose and the constitutional basis of the patent system. The consideration given by an inventor in exchange for his monopoly is, constitutionally, either the disclosure of his invention or the establishment of a new manufacture. The Board, through the mouth of its president, has now recognised officially a third kind of consideration, namely, a money payment to the Crown, and thus has violated flagrantly the spirit, if not the letter, of the Statute of Monopolies, which is one of the bulwarks of English liberty.

No doubt, like Courteline's *Directeur des Dons et Legs*, the Board only asks that its tranquillity be not troubled, and feels "la rage justement exaltée du monsieur qui a fait l'impossible et au delà pour être agréable à tout le monde, qui a semé sans compter l'or des bonnes paroles et des sourires pleins de promesses, et dont une brute malfaisante vient troubler la bonne petite existence reglée au mieux de l'intérêt général"! So that, whatever the nature of the Sargant Committee's report, and pending its issue, one may well ask whether the Board of Trade will not always be content merely to wipe the floor a little, from time to time, when the pot of public indignation boils over, or whether it will some day begin to deal generously with the cause of these ebullitions.

For our guidance in answering this question, we have only a few facts. The most interesting of these is the fact that as a contribution to the £60,000,000 which is to be borrowed from the Exchequer for expenditure in unemployment benefit, the Patent Office surplus is being extracted from struggling patentees by a sacrifice of administrative efficiency which holds up for a year or more the exploitation of those inventions upon which employment in an industrial country directly depends. This appears to be the only relationship between inventions and unemployment which is recognised by the responsible authority.

Race Crossing in Jamaica.

Race Crossing in Jamaica. By C. B. Davenport and Morris Steggerda, in collaboration with F. G. Benedict, Lawrence H. Snyder, Arnold Gesell, Inez Dunkelberger Steggerda and many Residents of the Colony of Jamaica. (Publication No. 395.) Pp. ix + 516 + 29 plates. (Washington, D.C.: Carnegie Institution, 1929.) 7.00 dollars.

IF length of title, weight of names, and number of printed pages can make a great book, this work should certainly be such. An 'abstract' printed at the back of the title tells us that the work is a *quantitative* study of three groups of agricultural Jamaican adults: blacks, whites, and the hybrids between them. Further, that the *variability* of each race and sex in respect to each bodily dimension and many bodily organs is discussed. We are also informed that it appears that mental traits which seem to have a genetic basis vary just as morphological traits do. In some sensory tests the blacks are superior to whites; in some intellectual tests the reverse is found. A portion of the hybrids are mentally inferior to the blacks. The studies embraced in the book are "morphological, physiological, psychological, developmental, and eugenical".

Now it will be seen from what we have cited from this abstract that the book claims to deal quantitatively with the type and *variation* of blacks, whites, and their hybrids. In other words, it is an anthropometric study and must be subjected to the accepted canons of biometric criticism. Let us first endeavour to ascertain the purpose that the numerous investigators concerned in the production of this work set before themselves. It appears to be the comparison of the White with the Negro and of both with the hybrid between them, in as many characteristics as can be conveniently measured. Now in order to do this we must first obtain (i) adequate-sized homogeneous samples of the three classes, and (ii) we must be acquainted with the genetic history of the hybrid. We must know whether he or she belongs to the F_1 or F_2 generation, etc., or whether there have, or have not, been back-crosses. Neither of these conditions appears to us to have been even approximately fulfilled.

The numerous authors, so far as we can judge, have paid no attention to the size of their samples. For the 'adults' the following table of numbers measured will emphasise what we mean:

Race.	Males.	Females.
Blacks	54	51
Browns	93	72
Whites	50	50

Even within these anthropometrically extremely small groups, there is no homogeneity. To begin with, the classification appears to be by skin colour, and is subject to personal equation. Several of the authors are Mendelians and believe in segregation in the F_2 generation. What is to be done, or has been done, with the 'pass-for-whites'? And, if we accept Mendelian segregation, a black-skinned person or a 'pass-for-white' may be respectively as close to the white or as close to the black race as any 'brown'. The fact is that Jamaica with its centuries of racial intermixture is the last place where a study of the relative physical and mental traits of White and Negro can be made. At least 500, better 1000, Europeans of reasonably homogeneous race should have been compared with the same number of West African Negroes. Take, for example, the 50 male 'whites'. Of these, 23 were agricultural workers, the bulk of them coming from Seaford and probably of *German* descent; 19 were able-bodied seamen, said to be 'huge men' of English descent, and 8 were office workers from Kingston. Their ages varied from eighteen to forty. Although whites do not reach their prime for most characters before 25-26 years, no correction is made for age. The 54 male 'blacks' are equally heterogeneous in age, social class, and environment, consisting of small groups of students, cultivators, firemen, candidates for the police force, and prisoners. Such characters as weight and stature are compared for mixed groups like these.

The authors do not hesitate to calculate percentages for one, two, or three individuals. For example, they conclude on material such as this, and after deducting a round 4 lb. for the minimum clothing in which the whites were measured and *not* taking off 0·5 lb. for the residue of the blacks' clothing, that browns and whites have about the same mean weight while "the blacks are much the heaviest, on the average" (p. 49). They may be or may not be, but the present data prove nothing. Deducting the 0·5 lb., the blacks are 145·70 lb. ± 1·69 lb. and the whites 140·30 lb. ± 2·24 lb. The difference is accordingly 5·40 lb. ± 2·98 lb., or it is only 1·8 times its probable error, which cannot be considered of any significance.* On such heterogeneous small

* Weight does not reach its maximum in the white until about forty years. Hence if there were any significant difference between the above numbers of blacks and whites, it would have no racial meaning until correction had been made for the individual ages in the two groups.

populations with resulting high standard deviations and consequently large probable errors, no inference as to differences in type can be safely drawn. Again, with cephalic index, what scientific conclusions can possibly be deduced from a small group of 50 whites admittedly of mixed German and English descents, and from a group of 54 blacks, who if they have no white blood in them—which may well be doubted—may originally have come from many districts of Africa ?

Strong adverse criticism can easily be made of nearly all the anthropometric measurements in the volume, and this not only on account of the race, age, and class heterogeneities of the small samples used, but also on the basis of the descriptions as to how some of the measurements themselves were taken. Consider such a statement as the following:

"With a soft lead pencil, a line was drawn from the base of the orbit to the tragion, which is known as the 'Frankfort Horizontal'. The individual was informed of the importance of this line, and that his head was always to be held in a particular position. The individual was placed in the proper position and asked to remain quiet. Another line was drawn slightly below the glabella, and this represented for this study the nasion" (p. 20).

Anything more obscure it is hard to conceive, and the plates show that the photographs, so far from being standardised, were taken with the head and even the body with every variety of inclination and tilt—they are useless for anthropometric purposes. Even the light has not been studied by the photographer. For example, on Plate 13 two apparently complete blacks (if we are to judge by the colour of face and hands) are seemingly the parents of three thoroughly white daughters—a strong argument, if we could trust the photographs, in favour of Mendelian segregation ! On Plate 27 we are introduced to a boy with a white face and black knees, the son of a brown mother. We have not succeeded in finding any comment on this remarkable photograph. Was the boy piebald ?

When we come to basal metabolism, the author of this section has no hesitation in computing pulse rate, respiration rate, and basal metabolism on *eight* male blacks, and publishes standard deviations and probable errors for this sample of eight !

In discussion of the blood-groups we are suddenly confronted with a sample of 144 Jamaicans (147 in the text, 144 in Table 193, p. 277). We are not told how they were selected nor what proportions of whites, browns, and blacks occur in this number, but the 144 "Jamaicans" are classed with other presumably pure black and brown races. When we come to muscular strength as hand-grip, the numbers dealt with are 12 blacks, 25 browns, and 21 whites. On such numbers standard deviations and probable errors are computed. The results are 43·80 kgm. $\pm$ 1·40 for blacks and 41·96 kgm. $\pm$ 0·84 for whites (p. 274). The difference is 1·84 with a probable error of 1·63. The authors remark that "the blacks and browns exerted more pressure than the whites ; although it is not certan that the difference is significant". It certainly is not, and no such small heterogeneous samples could be expected to give anything significant. The twelve blacks are divided into twelve grades: four of these contain a single black, four two blacks, and four no blacks, and the percentages of these grade frequencies on the total of twelve are then tabled to two places of decimals ! The authors seem unaware that the percentage 8·33 of 1 in 12 has a standard error of 8·00 and the percentage of 2 in 12 a standard error of 10·07. In other words, both are wholly unreliable.

In the case of the mental tests, we have exactly the same inadequacy of numbers ; there are, indeed, cases in which only 6 or 7 whites were tested, and the authors do not hesitate to calculate means and standard deviations with their probable errors on such series. A more valuable result, based, however, on *only* 33 cases, is a correlation between skin colour and nasal index * of 0·477 $\pm$ 0·091 for blacks. The authors term this "an astounding result" (p. 296) ; presumably because they are thinking in terms of independent Mendelian factors. They remark : "It is possible that one of the factors for brown skin colour may reside in the same chromosome with a factor for broad nose, so that the two tend to be inherited together—are linked. Correlation is, however, not the criterion for linkage." Some persons may prefer to believe that some of the 33 blacks were not pure Negroes, and just as their skin colour had been lightened by European admixture, so their chamærrhinia had been diluted by European leptorrhinia. One of the most remarkable anthropometric processes is that adopted on pp. 257-259 ; no justification appears to be provided for it. Hair colour is divided into five classes—(i) black ; (ii) dark brown ; (iii) medium brown ; (iv) light brown ; (v) flaxen—and immediately below we find the means, standard deviations and probable errors presumably of hair colour. After some puzzling we find out that these

* Unfortunately, the correlation table is not published. It would appear that there were only four categories of skin colour.

had been obtained by using the index numbers of the above classes as the quantitative measure of 'blondness'.* In Table 176 'red hair' (vi) was added in with an intensity of blondness 6, that is, as blonder than 'flaxen'. The average red hair of whites has intensity of pigment granules, which places it among the brown hair group. No scale of melanotic pigment granules would distribute their intensity in black and flaxen hairs in the inverse ratio of 1 to 6.

As the points we have been endeavouring to emphasise in this notice turn on the heterogeneity as to age and race and its effect on 'small samples', we think it well to point out the fallacies which may arise, when arguments are based on such small samples by a final illustration.

We take the author's table for change of stature variability with age.

STANDARD DEVIATIONS OF FEMALE WHITES FOR STATURE AT VARIOUS AGES IN CENTIMETRES.

Age.	Book under Review.		British School Girls.	
	No.	Standard Deviation and its Probable Error.	No.	Standard Deviation and its Probable Error.
5	..	..	894	6·13±0·10

15	5	4·00±0·86	..	..
Total	83	..	30,965	..

On the left we have the data for white girls from the present research, and on the right data for adequate numbers of British girls.

We have enclosed the last figures for girls of fourteen years on the right in square brackets because, during the age-year 14 to 15, 2000 of the girls had left school, and the remainder were a relatively stringent selection with lesser variability. Now compare the two variability columns. On the right we see a steadily increasing variability in stature as the girls increase in age. On the left we have an irregularity of variability, absolutely screening by the inadequate numbers in the age classes any discovery of the law so obvious on the right! Yet it is on the basis of such series screening the continuous increase of variability with age that our authors draw the conclusion that: "It is apparent, also that among females, the blacks and browns are more variable than the whites between twelve and fifteen years of age" (p. 379).

The only thing that is apparent in the whole of this lengthy treatise is that the samples are too small and drawn from too heterogeneous a population to provide any trustworthy conclusions at all. There are sound biometricians and anthropologists in the United States, and it would have seemed worth the while of the Carnegie Institution of Washington to have placed the manuscript of this work before them before authorising its publication. We can scarcely believe that even some of those whose names appear on the title-page as an "Advisory Committee" have seen before issue this book with the biometric errors which abound in its pages.

KARL PEARSON.

* Any such order of classification neglects the existence of two fundamental hair pigments.

Strong and Weak Electrolytes.

The Conductivity of Solutions and the Modern Dissociation Theory. By Cecil W. Davies. Pp. viii + 204. (London: Chapman and Hall, Ltd., 1930.) 15*s*. net.

THE theory of reversible ionisation, advanced by Arrhenius in 1887, owed its widespread acceptance to the fallacy that the degree of dissociation of a salt can be calculated independently from the conductivity and the osmotic properties of its solutions. In more recent years the concordance between the values deduced in these two ways has been denounced on the grounds that it has no sound theoretical basis and that the numbers cited by Ostwald and others do not in fact provide the experimental justification that was claimed for them in the days when the study of dilute solutions was heralded as the birth of a new science of physical chemistry.

Although tentative attacks on Arrhenius's theory had been made in pre-War days by Sutherland and by Milner, the detonation of the charge was delayed by the distracting influences of the War-period, and the apparently final shattering of the theory did not take place until 1923, when Debye and Hückel showed how the waning conductivity of strong electrolytes with decreasing dilution could be explained by changes in the mobility of the ions instead of in their number. Their formula had the merit of providing a theoretical foundation for the experimental law, discovered by Kohlrausch in 1900, that the fall in equivalent conductivity is proportional to the square root of the concentration, $\Lambda_0 - \Lambda_c = b\sqrt{c}$, so that a straight line is obtained by plotting Λ against $\sqrt{c}$. This relation, which

was illustrated by Hartley in NATURE of Feb. 26, 1927, p. 322, had not hitherto received the theoretical justification which Kohlrausch had anticipated, and its interpretation by Debye and Hückel in terms of well-established phenomena was at least as important as the discovery of Ostwald's dilution law for weak electrolytes such as acetic acid. Consequently, in spite of the fact that the predicted slopes of the lines were quite different from those found experimentally, the theory of complete ionisation was received with the same enthusiasm which had been accorded thirty-six years before to the theory of reversible ionisation.

The general acceptance of the new theory (which was obviously in harmony with the ionic structure assigned by X-ray analysis to the majority of crystalline salts) was a noteworthy feature of the general discussion on strong electrolytes held at Oxford in April 1927 under the auspices of the Faraday Society (see NATURE, May 7, 1927, p. 676). On that occasion, indeed, the main obstacle to its general acceptance was removed by Onsager's development of a formula, in which, by allowing for the effects of molecular bombardment as manifested in the Brownian movement, the slope of the lines referred to above was increased to a point at which it appeared to correspond closely with that which is actually observed in solutions, provided that these are sufficiently dilute.

So recently as three years ago, then, it was possible to suppose that salts which crystallise in ionic aggregates are not merely ionised completely in solution, but also are dissociated almost completely into free ions, since calculation indicated that the proportion of ionic doublets was almost negligible. This position, however, is no longer tenable in view of the experimental work done by A. R. Martin and others, since it must now be admitted that, when the Debye-Hückel-Onsager correction for electrostriction has been applied to the mobilities of the ions, the resulting ionic concentrations are not 100 per cent except at extreme dilution, and that (especially in non-aqueous solutions) there is still a diminishing of equivalent conductivity with decreasing dilution which must be explained by decreasing dissociation of the molecules (or ionic aggregates) of the solute, and which appears to apply to Kirch Ostwald's dilution law just as well as it does to weak acids and bases. The time is thoroughly ripe for a further review of the situation, perhaps under form of a general discussion on weak electrolytes, at which the impression created at the previous Oxford discussion could be corrected, and brought to date.

From this point of view the appearance of Mr. Davies's book is very opportune. During recent years, the authors of a number of books on physical chemistry were in the unfortunate position of being afraid to scrap the deductions made by applying the law of mass action to electrolytes, but were forced to admit (usually in a separate chapter !) that the theory of electrostriction had made these calculations both obsolete and irrelevant. It was, therefore, possible to claim as a novelty a treatment of the subject in which the existence of reversible ionisation was admitted as freely as that of non-reversible ionisation. This contention, which is rapidly becoming quite orthodox, is the fundamental creed of Mr. Davies's book, since he admits that " two types of electrolytes will be looked for ", and after citing the evidence in support of Onsager's equation, goes on to say that " there is every indication that in solvents of low dielectric constant no salts are completely dissociated at attainable dilutions ".

This dual aspect of the phenomena makes the conductivity of solutions a more complex problem than it was when Kohlrausch wrote his " Leitvermögen ", since the activities as well as the concentrations of the ions must be taken into account when calculating such apparently simple quantities as the solvent-correction in dilute solutions or the limiting values of the ionic mobilities, as well as when trying to deduce the coefficient of ionisation or the equivalent conductivity of solutions of finite dilution. These problems are treated, perhaps for the first time in a systematic manner, in Mr. Davies's work, and it can be asserted that no worker who undertakes research in this field will feel quite safe in his deductions unless he has weighed up the considerations which are here advanced. For this reason, the book can be commended heartily to the specialist as well as to the general student of chemistry, since both will find in it facts and deductions which are too important to be overlooked.

T. M. LOWRY.

Science in Soviet Russia.

Science in Soviet Russia. By J. G. Crowther. Pp. 128 + 13 plates. (London: Williams and Norgate, Ltd., 1930.) 7*s*. 6*d*. net.

MR. CROWTHER is one of the few English men of science who have ventured into Russia in recent years. He was impressed by the extent of the researches projected and prosecuted in the various institutes which he visited. It appears that the study of the different branches

of science have been placed in contact with the social institutions to which they are naturally related. Thus, all bodies concerned with applied botany are controlled by the State Department of Agriculture. The thousand workers at botany work to one planned scheme. Unnecessary overlapping has been reduced by centralisation. Institutions conducting researches of industrial value receive their endowments from the Supreme Economic Council and they work in contact with the industry upon which the research directly bears.

With regard to emoluments it would appear that men of science are among the better paid workers and their conditions are still improving. Engineers are the best paid and the highest salary quoted is £3500 per annum. Nevertheless, even the lesser paid research workers concentrate upon their tasks and attain a high degree of skill and efficiency. There is still a shortage of trained investigators, especially in physics and engineering, and the author suggests that there is scope for young English graduates to gain valuable experience in posts available in the Soviet's numerous electrical works which are in course of construction and extension.

Among the work in progress Mr. Crowther mentions the speeding-up of tobacco fermentation, the isolation of sulphur from the dioxide obtained in roasting copper ores, the synthesis and preparation of drugs hitherto imported from abroad, petroleum refining, and improved technique in the preservation of wood. Apparently investigations of a purely academic nature are not countenanced, although the term 'applied science' is being interpreted very broadly. At the moment large electro-technical developments are being made as a part of the five years' industrialisation plan. Power plants and technical factories are being erected all over the Union, and it would seem that Russia is making notable contributions to the progress and development of science. Russia is a vast country with well above a hundred million inhabitants, and although Mr. Crowther has seen many scientific institutes in the two chief centres, Leningrad and Moscow, his tour was restricted to less than four weeks. Furthermore, without a knowledge of Russian he was dependent on his interpreters, so that the value of his impressions is limited. Nevertheless, the information concerning the condition of Russian men of science and the progress of their researches is at least of interest to their colleagues in the rest of the world.

Our Bookshelf.

Trattato di chimica generale ed applicata all' industria. Per Prof. Ettore Molinari. Vol. 2: *Chimica organica.* Parte seconda. Quarta edizione riveduta ed ampliata. Pp. xvi + 661-1567. (Milano: Ulrico Hoepli, 1930.) 80 lire.

THE death of Molinari nearly four years ago doubtless accounts for the delay in the completion of the new edition of his "Organic Chemistry", the first part of which appeared in 1927. The alterations necessary to bring the contents of this second part up-to-date are due to the author's three sons, working in conjunction with Profs. Bargellini and Contardi. The subjects dealt with in the present volume comprise oils, fats, and waxes, carbohydrates, ring compounds, textile fibres, and proteins. The general scheme of the book, with its inclusion of numerous data regarding production, importation and exportation of raw materials and manufactured products, must by this time be generally known to chemists. The only new feature requiring comment is the insertion of large-scale flow sheets of an olive-oil refinery and of a sugar factory. Similar sheets for other processes might with advantage be given in any future edition.

The volume now published contains 860 pages of text, much of it of small type, but in view of the multiplicity of subjects treated—some quite foreign to the ordinary text-book of pure, or even of applied, organic chemistry—certain of these are necessarily dealt with all too briefly. Thus, vitamins are dismissed in less than two pages, and although the general characteristics of these substances are indicated, important recent results in this field are entirely omitted.

The full index supplied covers the two parts of the "Organic Chemistry", and the price of the whole work amounts to 125 lire, which is modest enough. The book is one which may be recommended to all engaged in chemical industry.

The Use of Iodine and its Compounds in Veterinary Practice. By Lieut.-Col. H. A. Reid. Pp. 88. (London: De Gruchy and Co., Ltd., 1929.) 3*s.* 6*d.*

ALTHOUGH the essential rôle played by minerals in animal metabolism has been recognised for many years, it is only recently that the importance of iodine in the diet has been stressed. The requirement of animals for iodine compounds is only small; nevertheless, a deficiency of such compounds in the diet may lead to acute pathological conditions in animals and human beings. Iodine deficiency, for example, has been shown to be the fundamental cause of goitre, an ailment which is especially prevalent in districts where the soil and water are notably deficient in iodides. Such iodine-deficient conditions are found in parts of the northern half of the United States, in which localities it is now customary to iodise the public water supplies or to insist on the use of iodised table salt.

In the book under review, Col. Reid has gathered

together, in very readable form, the conclusions which have been drawn from numerous investigations into the functions of iodine in maintaining health in animals. The use of iodine, and various compounds of this element, for antiseptic purposes is first dealt with. The author then proceeds to discuss the diseases of iodine deficiency, showing how these diseases are amenable to treatment by iodine and its compounds. Further sections deal with the influence of iodides in nutrition and on growth and reproduction. Mention should also be made of the useful bibliography at the end of the volume. Col. Reid's book should be read by all, whether scientific workers or laymen, who are interested in health problems and the future virility of the race.

An Introduction to Physical Anthropology. By E. P. Stibbe. Pp. vii + 199. (London: Edward Arnold and Co., 1930.) 12*s.* 6*d.* net.

ANYONE conversant with the needs of those entering upon a course of anthropological study will be aware of the difficulty in finding a satisfactory textbook in physical anthropology. Not that there are no text-books in existence; but they are for the most part too detailed for the beginner and recent advances have made them out-of-date. Dr. Stibbe's "Introduction to Physical Anthropology" meets the need admirably. It deals with its subject matter under the heads zoological, palæontological, and ethnological. In the first we are introduced to the methods and findings of comparative morphology; in the second, the palæontologist, geologist, and archæologist are called to the assistance of the anatomist in elucidating the origin, evolution, and antiquity of man; and in the third, racial characters and distribution are considered. Useful instructions for practical work and a glossary of technical terms complete a volume which should fulfil all the requirements of a beginner in anthropological studies, so far as this is possible in a textbook; for one of the most useful features in Dr. Stibbe's book is his insistence on the necessity for handling specimens in a laboratory and for constant practice in measuring the living. The arrangement of the text in the zoological section in which man and the apes are compared in detail will be found most helpful. The author himself would be the first to agree how much his text-book owes to the teaching of Prof. Elliot Smith, and perhaps its greatest merit is the way in which it leads the student inevitably to an intelligent appreciation of Elliot Smith's eminent services to anthropology.

Cours de chimie-physique. Par Prof. L. Gay. Tome 1. Pp. xii + 705. (Paris: Hermann et Cie, 1930.) 85 francs.

THIS volume is the first of a series of three, of which the first two are to be devoted to thermodynamics and the third to classical physical chemistry (electricity and magnetism, colloids, chemical kinetics, catalysis, radiant energy, and photochemistry). The modern and controversial questions of radioactivity, atomic and molecular structure, and the classification of the elements, are reserved for treatment in a later work. The first part of the present volume, covering nine chapters and 220 pages, is devoted to pure thermodynamics and thermochemistry. The second part, covering six chapters and 160 pages, unites rather ingeniously the study of the dilute gaseous state and of the crystalline state. The third part (three chapters and about 100 pages), dealing with osmosis and the phase rule, may be regarded as an introduction to the study of solutions, whilst the fourth part (five chapters and about 160 pages) is devoted to the study of pure substances, including the questions of continuity of state, the Brownian movement, and allotropy. An appendix of about 40 pages is devoted to problems, mainly of an industrial type, for which solutions as well as answers are given, and these may very well prove to be one of the most valuable features of the book.

Antarctic Adventure and Research. By Prof. Griffith Taylor. (Appleton New World of Science Series.) Pp. xi + 245. (New York and London: D. Appleton and Co., 1930.) 6*s.* net.

THERE are few general volumes on polar regions that deal with the scientific problems rather than with the adventure of exploration. This makes Prof. Taylor's volume welcome. As the title indicates, the adventure is not neglected, for about a third of the book treats of the history of Antarctic exploration. The remainder treats of scientific aspects. Prof. Taylor devotes most attention to the Ross Sea area with which he has personal acquaintance, and his predilection for physiography leads him to devote most space to several excellent chapters on topography, scenery, and ice. The biology receives less attention and the chapter on whaling is very brief. There are many graphic diagrams by the author and a useful bibliography, which might, however, be enlarged by more references to the Graham Land area and the Weddell Sea. The book makes no attempt to treat the islands of the Southern Ocean, but for a brief general account of the Antarctic it can be recommended.

Practical Chemistry: for Advanced Students. By Arthur Sutcliffe. Pp. vii + 216. (London: John Murray, 1930.) 4*s.* 6*d.*

MR. SUTCLIFFE'S book is suitable for pupils preparing for higher school certificate and similar examinations. Elementary experiments are not described and much detail concerning manipulation has been omitted, since students of this standard will not require it. The course covers qualitative and quantitative analysis, inorganic and organic preparations, and some simple exercises in physical chemistry. The directions for the preparations are clear and adequate, and the section on qualitative analysis contains all the equations for the reactions and explanatory notes. The course is well planned and the book should prove successful in schools where work of this standard is done.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Ionisation Potential of Radon.

WE have determined the ionisation potential of radon, using the well-known method,[1] due to Hertz, of compensation of the negative space-charge by positive ions formed by accelerated electrons from a subsidiary cathode. This cathode was an equipotential one and differed only in slight details from that described by Hertz and Kloppers.[2] In the original apparatus of Hertz the accelerating grid forms a part of a box which receives the space-limited current from the chief cathode. We have modified this arrangement by introducing a separate accelerating grid which enabled us to measure directly the useful part of the subsidiary emission, that is, the number of electrons penetrating into the box. The contact potential correction of the apparatus was determined by calibrating it with pure xenon and krypton: it was found to be 2·6 volts.

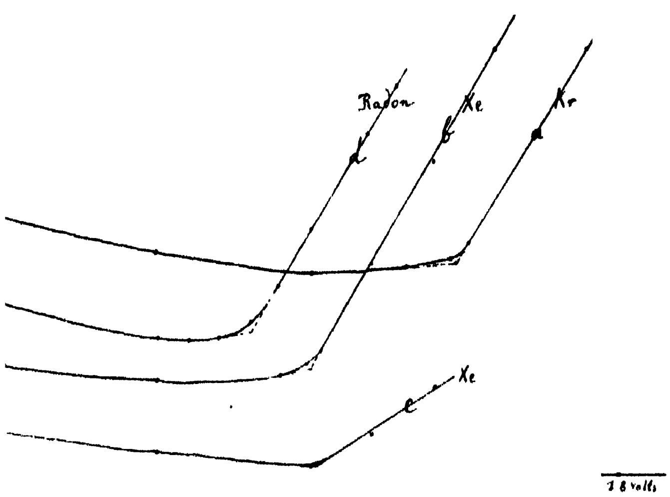

FIG. 1.

The quantity of radon used in different experiments was of the order of 300 millicuries. The volume of the apparatus with auxiliary parts being equal to about 250 c.c., the calculated pressure of radon was of the order of 0·8 bar, and one might think at first that the method would not be sensitive enough for such small quantities of gas. Preliminary experiments have shown, however, that it is quite easy to determine the ionisation potential of xenon when present at a pressure of 1 bar, and the sensitiveness of the method increases in a marked way with the atomic weight of the rare gas used for investigation. It ought also to be mentioned that at such low pressures the number of ions produced by the α-rays is negligibly small compared to the number of electrons involved in the experiment, so that radon can be treated as any other inactive gas.

Another important point was to make sure that the possible impurities of radon would not mask the appearance of discontinuities due to this gas.

We performed, therefore, a set of measurements in which special stress was laid on the purification of radon but not on the exact determination of the critical potential. The method of purification was the same as that previously described by one of us.[3] These experiments put beyond doubt the existence of an ionisation potential due to radon. This potential, in agreement with theoretical expectation, was found to be somewhat lower than that of xenon and therefore of any other permanent gas.

This circumstance facilitates essentially the work with radon. The only impurity which really matters is mercury vapour. Therefore in the final experiments we did not aim at a complete purification of radon, but used a trap kept in a bath at −120°, in order to get rid of the mercury vapour and a tube with caustic potash for absorbing carbon dioxide. The other details of the arrangement will be given in a later publication.

Curves obtained in the final experiments are shown in Fig. 1. In order to make the method more sensitive, the electronic current was nearly balanced against a steady current given by a potentiometer. On the curves the difference between the two currents is plotted against the accelerating potential of the subsidiary electrons. Curve *a* refers to krypton at a pressure of 7·2 bars, curve *b* to xenon at a pressure of 15 bars, curve *c* to xenon at a pressure of 1·3 bars, curve *d* to 250 millicuries of radon. The values of the ionisation potential of these gases corrected for the contact potential are 13·3, 11·4, and 10·6 volts respectively. The last value, that of radon, is in good agreement with the value 10·7 volts deduced recently by Rasmussen[4] from an investigation of the spectrum of radon.

Fine Structure in the Singlet Series of Mercury.

UP to the present no fine structure has been observed in the singlet series of mercury. In a recent communication to the Physical Society of London (*Proceedings*, August 1930) a description was given of the spectrum of mercury excited at low pressures by a high frequency electrodeless discharge. Amongst other effects it was found that the singlet series and intercombination lines due to transitions beginning on singlet levels, were strongly enhanced relative to the triplets. The line $6^1P_1 - 8^1S_0$ was examined for fine structure with a Fabry-Perot interferometer and found to be single and so narrow (half width $< 0·004$ A.) as to render it of great value in interferometric work.

As a result of recent improvements in experimental conditions, three new components have been detected, one faint and two very faint, the intervals being approximately:

$$-0·012 \quad 0 \quad +0·009 \quad +0·031 \text{ A.}$$

Since these only appear when the main line is heavily overexposed, they have practically no effect on the visibility of the fringes when normal exposures are used, and therefore should not detract from the usefulness of the line as a source. The next member of the same series $6^1P_1 - 9^1S_0$ is also complex.

Many other strengthened lines involving singlet levels show a complex structure; for example,

$$7^1S_0 - 8^1P_1,\ 7^1S_0 - 9^1P_1,\ 7^3S_1 - 8^1P_1,\ 7^3S_1 - 9^1P_1.$$

Three of the lines are shown in Fig. 1, including the unclassified line λ6123·78, the plate separation being chosen to show the widths of the multiplets before overlapping of orders occurs. The intervals between adjacent orders are marked, giving an indication of the separations. The closer components are completely separated for bigger gaps. The structure is not due to reversal, since it remains the same when viewing end-on through depths of vapour varying from 2 mm. to 50 cm.

The two members of the series $6^1S_0 - m^1P_1$ have a sextet structure, thus indicating that both initial and final levels are multiple since the maximum number of possible components when one level is single, is three, assuming the usual selection principle to hold.

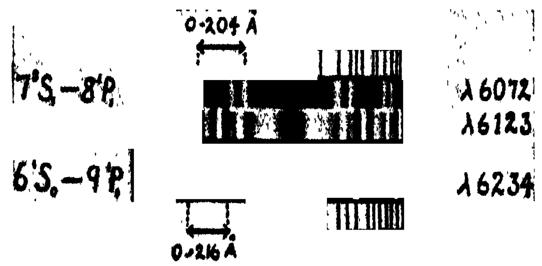

FIG. 1.—Fine structure in mercury spectrum. Fabry-Perot fringes, plate separation 9 mm.

As the final level is a $^1S_0$ level ($j = 0$) it ought to remain single, if nuclear spin is the cause of the fine structure. However, the observed structure shows that it is at least double. It is possible that this multiplicity is due to an isotope effect. This is not the simple mass isotope effect (variation in Rydberg constant with mass) as recently observed in neon, for in mercury this would give maximum separations of approximately 0·00001 A., which is very much smaller than that observed. Schüller and Brück (*Zeit. für Phys.*, **56**, 291; 1929) conclude that in a mixture of isotopes, only those with odd atomic weight possess nuclear spin. Assuming this true in mercury, then two $^1S_0$ levels will result, with f value $0+0=0$ for even atomic weights and $0+i=i$ for odd. If i has more than one value, the level becomes still more complex. A detailed analysis of the observed fine structure will be published shortly. The intensity ratios of the components are also being investigated.

Spectra of Doubly and Trebly Ionised Thallium.

CONTINUING our previous work on Tl II and Pb III, the spectra of Tl III and Tl IV have been under examination by us for some time past. A preliminary attempt, by the application of the X-ray doublet-laws, revealed a number of regularities consisting of mainly the regular doublet terms. As a result of further attempts, it has now been possible to identify the inverted ^2D term ($5d^96s^2$) and the quartet terms of ($5d^96s6p$) and ($5d^96s6d$) configurations. The starting point for the discovery of the inverted ^2D term was given by the identification of ν 76150, 81834, and 100452 as $6s'^2D - 7p^2P$. The super multiplet accompanying the electron transition $6p' \rightarrow 6d'$ contains about forty lines in the ultra-violet. A few combinations due to transitions $6p \rightarrow 7s$ have also been established. The ($5d^96s^2$) ^2D term interval is found to be 18618. The combinations that could not be identified are either very faint or out of range.

Thallium IV: The spectrum of trebly ionised thallium was recently studied by K. R. Rao, by Pattabhiramayya, and by J. E. Mack, who have all identified the triplets due to the combinations of $6s^3D$ and ^1D with $6p^3PFD$ and ^1FPD. As a result of attempts by one of us, it has been found possible to extend the analysis and identify the super multiplet due to the combination of $6p^3PFD$ with $7s^3D$ and ^1D.

In both these spectra the line intensities, term differences, and interval ratios are of the right order expected. A complete report will be published shortly elsewhere.

Raman Spectra of the Mercaptans.

AN investigation by me of the Raman effect in a series of mercaptans has yielded some noteworthy results. As is well known, the mercaptans are chemically analogous to the alcohols, the SH group in them replacing the OH group characteristic of the alcohols. The oscillation of the SH group comes out prominently as an intense though somewhat diffuse line in the Raman spectra of all the mercaptans examined, with a frequency shift of 2574 wave numbers. This is in marked contrast to the behaviour of the OH group, of which the broad band ($\nu = 3400$ cm.$^{-1}$ approximately) appears only in water and methyl alcohol but not in the higher alcohols. Another strong line appears with all the mercaptans giving a frequency shift of about 657 wave numbers, and is evidently due to the oscillation of the CS group; it is in the same position as the most intense line in the spectrum of carbon disulphide. The analogous oscillation of the CO group with a frequency of about 1050 wave numbers appears strongly in methyl alcohol but only very weakly in the higher alcohols.

These differences in the behaviour of the SH and OH groups are sufficiently remarkable. Another notable feature is the unusual width and diffuseness of the lines ascribable to the oscillations of the carbon chain in the mercaptans. This character is presumably referable to the influence of the sulphur atom on these oscillations.

Hydrion Concentration of Rain and Potable Water.

FOR a study of the hydrion concentration of rain water New Milton appears to offer certain advantages. It is a small town equidistant between the Channel and the New Forest, about ten miles east of Bournemouth and seventeen miles south-west of Southampton, and it has the reputation of enjoying particularly pure and fresh air. For the past year and a half the hydrion concentration (pH) of the rain has been recorded together with the general direction of the wind, these observations having been made with the view to their possible value as part of the general problem of the influence of meteorological conditions upon plant diseases.

Indicators supplied by British Drug Houses, Ltd., were used to test the pH of rain collected from various plants and from two collectors about nine inches in diameter.

The pH of the water obtained from the collectors and from the plants varied between 5·5 and 7·6, with practically all intermediate values. The readings taken simultaneously from the collectors and from the

plants were sometimes identical and at other times very different values were obtained. The same remark applies to a comparison of the unboiled (*U.B.*) and the boiled (*B.*) water from the different sources. A few typical examples may be cited.

Date.	Wind.	Collector 1.		Collector 2.		Plant 1.		Plant 2.	
		U.B.	*B.*	*U.B.*	*B.*	*U.B.*	*B.*	*U.B.*	*B.*
Jan. 11	W.	7·2	7·2	7·2	7·2	7·2	7·2	7·2	7·2
Jan. 21	E.	5·0	5·0	5·0	5·0	6·4	6·4	6·0	6·6
Jan. 27	N.	5·2	5·2	6·2	7·0	5·2	5·2	6·2	5·2
Feb. 5	N.	6·0	6·0	6·0	6·0	7·0	7·4	6·0	6·0
Mar. 5	S.E.	5·2	5·0	5·0	5·0	6·2	6·4	6·0	6·0
May 13	W.	5·8	6·8	5·8	6·4	6·6	7·0		
June 22	S.W.	7·4	7·4	6·6	6·8	7·4	7·4	6·4	6·0

It is difficult to interpret the capricious variations obtained; possibly extraneous matter and dissolved gases (for example, carbon dioxide) might have some effect. The means at my disposal have not enabled me to make chemical analyses. Although the number of observations are not of sufficient extent to enable any general theory to be advanced, yet it appears that the rain borne upon winds direct from the sea is practically neutral, while that from the direction of towns or long stretches of country tends to become acid.

The data so far obtained indicate that wide variations in *p*H are to be expected in the rain falling upon living plants, even when growing close together, and the extent to which these variations may affect the micro-organisms present upon plants ("Bacteria in Relation to Plant Pathology", presidential address, British Mycological Society, 1909) might be the subject of an important research. To the well-known factors of atmospheric humidity, temperature, and light intensity which influence the infection of the host by parasitic fungi, the hydrion concentration of the surface moisture upon the plant may require to be added. This problem of the influence of the *p*H of a medium upon the germination of fungus spores is being made the subject of investigation by Mr. A. W. Bartlett, at Newcastle-upon-Tyne.

The hydrion concentration of potable water was tested by samples taken from various parts of England. The extreme readings were *p*H 5·0 and 9·0, the former obtained from wells which give good potable water, the latter from house pipe supply. Intermediate gradations were recorded in both these sources of supply, but good well water generally indicated more acidity than that from a pipe supply.

Often a great difference of *p*H is found between the unboiled and boiled samples from the same source. The pipe supply from one company varied from 6·8 to 8·2, while the boiled sample was practically always uniform at 9·0. It was found that an unboiled sample, as drawn from the tap, registered 7·4 but after standing some hours (protected from dust) it registered 9·0. It is of some interest to note that when breath was blown through the latter the original determination was restored. This fact is an indication that the hydrion concentration of a pipe supply may be affected by the carbon dioxide dissolved in the water. Thus, water from the same supply drawn directly from the tap or from an open cistern might have very different properties. Possibly the *p*H of a water under pressure in pipes might be a favourable medium for certain bacteria, while the same water after exposure to the air might be inimical to their activity.

While filtration has been shown to be of the highest importance in removing micro-organisms from water, the suggestion may be offered that the hydrion concentration should also be considered as a limiting factor for their growth. M. C. POTTER.

Animal Plasticity and Environment.

WHILE recently making a zoological collection in the Sevoke River in the Teesta Valley at the base of the Darjiling Himalayas, I observed remarkable differences between the individuals of a Cobitid fish, *Acanthophthalmus pangia* (H. B.), collected from two diverse 'niches' in the same habitat. In Fig. 1 are shown the two types of individuals. The chief difference, which is readily noticeable in the two drawings, is that in the lower drawing the ventral fins are present, while in the upper these structures are totally absent. There are also other differences of a minor nature; for example, the extent of the nasal flap and the form of the caudal fin. Two specimens * possessing ventral fins were obtained from among pebbles and shingle in a swift current, whereas 18 examples devoid of ventral fins were netted from among debris at the bottom of pools in the course of the stream.

It seems to me very likely that the structural differences in the specimens are correlated with the two types of environment in which the fish lives. If this be so, a very interesting taxonomic problem arises. In 1860, Blyth [1] established the genus *Apua* on two specimens which he distinguished from *Pangio* (=*Acanthophthalmus*) primarily by the total absence of the ventral fins. Both Günther [2] and Day [3] recognised Blyth's genus, and evidently regarded the

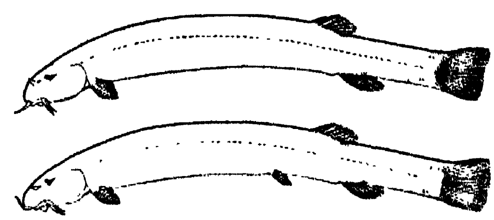

FIG. 1.—*Acanthophthalmus pangia*, × 1½.

absence of ventrals as a character of generic importance. Vinciguerra [4] considered *Apua* a synonym of *Acanthophthalmus*, and remarked that in the unique specimens of the former genus the ventrals must have been either overlooked or accidentally lost. In 1921, I published a note [5] on the occasional absence of paired fins in fishes and pointed out that *Apua* cannot stand distinct from *Acanthophthalmus*, and that the two specimens should be considered as abnormal so far as the absence of the ventrals is concerned.

Now arises the chief point for consideration. In view of the discovery of so many as eighteen examples from a specific habitat of *Acanthophthalmus pangia* without the ventral fins, what is the systematic position of *Apua*? Is *Apua* to be regarded as a distinct genus or should the specimens without the ventrals be considered as a 'habitat-variety' of *Acanthophthalmus pangia*? I am personally inclined to the latter view, and feel no justification in regarding the two kinds of individuals as separate species. As to the factors in the environment responsible for the loss of the ventrals, it is not possible to say much in the present state of our knowledge regarding animal ecology. It is probable, however, that the ventrals are an encumbrance for life among debris and are, therefore, suppressed. If this be so, then this case will be parallel to certain Chironomid and Trichopterous larvæ [6] that do not form their tubes or discard them when living in submerged debris. Some workers attribute the absence of the ventral fins in *Channa*, another genus of apodal fishes, to the habits of these fishes, but how far this is true I am unable to say at present.

* Special efforts were not made to obtain specimens possessing the ventral fins, as they are present in large number in the collection of the Zoological Survey of India.

The example cited above raises several important questions. Do these 'habitat-varieties' interbreed? If so, what is their progeny like? If not, then physiologically they are distinct species, though morphologically they are so similar. It is probable that after a freshet there is a mixing up of animals living in different habitats in a stream, and that on such occasions these two 'habitat-varieties' might interbreed. It is also known that torrential animals resort to slow waters (either in pools and puddles in the course of the stream or near the banks), and thus probably different 'habitat-varieties' come together at the time of breeding. If the progeny of these fishes include both types of individuals, how do they become segregated into their respective habitats? If, on the other hand, the progeny are alike, do some of them lose their fins after segregation into different habitats?

Siliceous Shells of Protozoa.

WE regret that circumstances have prevented an earlier reply to Prof. T. D. A. Cockerell's letter published in NATURE of June 28. In our opinion, there can be no question of either convergent or divergent evolution in the case of organisms belonging to separate families as widely separated as *Miliolina* and *Miliammina*. We thought we had made their absence of relationship sufficiently clear by the statement that *Miliammina* was a siliceous isomorph of *Miliolina*, isomorphism being understood among rhizopodists, at any rate, to mean the development of similar structures in unrelated organisms owing to unknown physical or biological conditions.

Even the American school of rhizopodists, who are so addicted to the construction of more or less imaginary 'family trees', would hesitate before suggesting a common ancestor for the two genera. At any rate we should have to go a very long way back, and probably to a theoretical non-testaceous reticularian, to find an organism capable of evolution into such widely differentiated structures, for the porcellanous Miliolidæ have existed since Carboniferous times, and *Silicosigmoilina*, a close relative of *Miliammina*, occurs in the upper Cretaceous.

The difference in the shell structures of the two genera is fundamental. The Milioline shell is normally smooth and porcellanous, but there are many species which habitually incorporate mineral particles to a greater or less extent in the outer coating of their porcellanous tests. Such a Milioline test consists of three distinct layers:

(1) an inner chitinous membrane surrounding the protoplasm;

(2) the normal porcellanous test formed of $CaCO_3$, and

(3) the outer siliceous coating.

The application of even a very weak solution of hydrochloric acid is sufficient to dissolve the middle calcareous layer, and the test is resolved into a little mud in which the chitinous membrane may be detected.

In the tests of the Silicininæ, however, there are but two layers, chitinous and sandy. Immersion in strong acid produces little or no effect.

Chapman evidently regarded his specimens from their external form as *Miliolina oblonga* (Montagu), and, very reasonably assuming that it was a local variety which had assumed the agglutinating habit (not previously recorded in *M. oblonga*), added var. *arenacea*. The fact remains that in the absence of chemical tests they were regarded by him, and by ourselves and others afterwards, as *Miliolina oblonga*, and we maintain that in removing his specimens to a different genus and family, we acted more correctly in conveying the specific name rather than a varietal name, which then became tautological and applicable indifferently to any of the species in the new genus.

We do not attach a great deal of importance to Prof. Cockerell's designation of *Miliammina arenacea* (Chapman) as the type species, but we regret that he should not have communicated with us before publication. Had he done so he would have learned that further investigations since the paper was written had shown that the distribution of Chapman's form was somewhat distinctive, and that it was intended to raise it to specific rank in the *Discovery* Report now in course of preparation. In that report it will appear as *Miliammina arenacea* (Chapman), while the much commoner and more widely distributed species, which is the true genotype, will become *Miliammina oblonga*, H. A. and E. (*non* Chapman).

Transition of Kinetic into Vibrational Energy by Collisions with Particles.

IN the work of Leipunsky and one of us[1] it was shown that dissociation of hydrogen molecules by collision with positive potassium, sodium, and lithium ions occurs only with such energies of the ions that the part of their energy transmitted (according to the energy and momentum law) to the hydrogen molecule is not 4·3 volt (dissociation energy), but 12·4 volt (exciting energy).

Recently one of us has repeated this experiment, using a Pirani gauge, which increased the sensitivity of the method tenfold. The result obtained was the same as that mentioned above. According to the usual point of view, dissociation by collision with a massive particle is a result of transition of kinetic energy into vibrational energy of the atoms of which the molecule consists.

We are thus forced, by the results of the abovementioned work, to admit that such an energy transition occurs, if at all, very seldom. It seems that the inverse process, recombination of hydrogen atoms by a triple collision, also occurs, not indeed at every collision, as well as recombination of bromine atoms, which is, by the by, effected by the addition of nitrogen and oxygen (diatomic molecules, which can receive vibrational energy), and not effected by helium and argon. It follows, therefore, that the transition of vibrational into kinetic energy also is not a process which proceeds readily.

To prove the correctness of the assumption that molecules dissociate by collisions with ions only when previously excited, we have tried to get dissociation of nitrogen by collision with positive ions. The exciting potential and the dissociation energy of nitrogen are very near one another. Accordingly, we have not observed any appreciable difference between the critical energy of the ions and the energy of dissociation of nitrogen. This shows that the results obtained for hydrogen are not experimental errors.

The necessity thus arises for a more detailed study of the mechanism of transition of kinetic into vibrational energy. It seems to us to be interesting (1) to study directly the distribution of speeds of the ions once reflected from monoatomic and diatomic molecules; (2) to study the critical potentials of the radiation of polar molecules excited by collisions with ions, and (3) to investigate the thermal capacity of a stream of diatomic gas, preserved from contact with the walls by a concentric stream of monoatomic gas.

We intend to carry out investigations in these directions. The question as to transition of kinetic into vibrational energy is a fundamental one in chemical kinetics. Therefore we intend also to determine the energy of ions at which begins the decay of some molecules, the kinetics of which follows the monomolecular law, as well as to determine at which energy of the ions some reactions begin which require a previous dissociation of one of the molecules.

Foaming of Beer.

SOME little time ago, seeking refreshment in a wayside tavern, I heard a man give an order in a most implacable manner, for a "half pint of bitter and in a dry glass if you don't mind". With great zest and concentrated attention this connoisseur drank his ale and departed, leaving me free to question the landlady on the merits of a dry glass. She explained that some people asked for a dry glass because they liked a head on their beer, and on occasion when Bass's, Guinness's, and the like were a bit fiery, they were compelled to wet the glasses to keep them down.

I have verified this fact by questions of other ale drinkers and I have discussed the matter with three physicists of standing to whom the matter was novel.

The froth on beer normally assumes a peaked cap, showing what might be the effects of a viscous drag on the sides of the glass, but the effect may not be due to viscosity so much as wetting action with film tensions against the glass walls. The matter is possibly worthy of investigation in connexion with industrial processes where foaming liquids are used, and more generally, in connexion with ebullition, the wetting of the walls by a liquid different from that contained in the vessel may be interesting or useful.

I confess that I write this with mischievous but respectful curiosity. Is there more than one very important journal to which such a contribution could be addressed?

H. S. ROWELL.

39 Spencer Road,
Chiswick, W.4.

THE foaming or frothing of beer has been discussed fairly extensively from time to time, although the point now raised by Dr. Rowell does not appear to have been specifically mentioned. The actual frothing is, no doubt, due to a lowering of the surface tension of the beer, but the primary cause of this lowering has not been definitely established. It is most likely due to the concentration of certain dissolved constituents, such as peptones and albumoses, being greater in the surface layers of the beer than in the bulk of the beer. The retention of the dissolved carbon dioxide in the froth may also assist in the formation of the 'head', although this view is not accepted by some observers. Very small traces of impurities, such as oil, grease, or higher alcohols, disturb surface tension, and the wetted surface of a glass may act similarly.

At the Government Laboratory we have carried out a few experiments with a number of ales and stouts, and the results agree with the facts stated in the early portion of Dr. Rowell's letter, although in some instances the difference between the size of the 'head' in the 'wet' and 'dry' glasses was not very marked.

R. ROBERTSON.

Infection of *Phlebotomus perniciosus* Newstead with *Leishmania infantum*.

ALTHOUGH a considerable amount of research has been carried out in recent years on the transmission of kala-azar in China and India, very little has been added to the problem of the transmission of infantile kala-azar in the Mediterranean basin, apart from the infection of *Phlebotomus papatasii*, *P. perniciosus* var., and *P. major* on cultures of *Leishmania infantum*.

Working in Catania in Prof. Longo's clinic, we were able to infect *P. papatasii* and *P. perniciosus* (wild and laboratory bred) on a Chinese hamster infected with local strains of *L. infantum* during the earliest stages of the infection.

Out of 18 ♀♀ *P. perniciosus* (5 wild and 13 laboratory bred), 15, that is, 83 per cent, became infected. Control, 319 ♀♀ wild *P. perniciosus* were dissected and found negative. Out of 123 ♀♀ *P. papatasii* (51 wild and 72 laboratory bred) fed on the same hamster, only one became infected. Control, 2694 ♀♀ wild *P. papatasii* were dissected and found negative.

In both *P. perniciosus* and *P. papatasii* the flagellates tended to adopt an anterior position; in *P. perniciosus* at a temperature of 29° C. to 30° C. flagellates were found in the pharynx three and a half days after the infecting feed.

Wild *P. papatasii* was also infected by feeding through membranes on infected human bone marrow. It was found that there was occasionally a slight infection rate if smears of the bone marrow showed an average of at least one Leishman-Donovan (L.D.) body per twenty fields (Oc. 4 Obj. $\frac{1}{12}$) and no infection with one L.D. body per forty fields. By culture methods we could demonstrate the presence of L.D. bodies in the circulating blood in almost 100 per cent of cases of infantile kala-azar (in some cases with only 5 c.mm. of blood), but a concentration as heavy as one L.D. body per forty fields in the blood has never yet been observed by anybody in this disease. *P. papatasii* can therefore be excluded as an important vector of *L. infantum*. Up to the present we have not succeeded in producing an infection rate of more than 26 per cent in wild *P. papatasii* after feeding on heavily infected bone marrow.

P. perniciosus takes on an average a much smaller feed than *P. papatasii*, and the high infection rate produced in *P. perniciosus* by relatively few L.D. bodies shows that *L. infantum* is particularly well adapted to this sandfly, which should be considered as a good carrier of kala-azar in Italy.

and Hebrew University of Jerusalem.

The Quantum and Vision.

THE statement is frequently made that one quantum of light delivered instantaneously is just sufficient to excite the sensation of vision. We have made some measurements on the subject, and find that this is not the case.

By working with a pinhole aperture in a light-tight room, we found that a steady source equivalent to

one-tenth candle at one kilometre is just sufficient to excite vision. When a sector was rotated in front of the pinhole, a source 16 times as strong as this acting for $\frac{1}{12}$ sec. or $\frac{1}{60}$ sec. according to the observer was sufficient to excite vision.

One-tenth candle at one kilometre delivers about $4{\cdot}51 \times 10^{-5}$ erg per sec. on a pupil of 45 sq. mm. area. Only about 1 per cent of this lies between 410$\mu\mu$ and 760$\mu\mu$. If we assume that the source has the same energy distribution as that of a black body at 2000° K, and use Hecht's values for the visibility of light to the dark adapted eye, we can obtain the distribution of the light of the source over the spectrum. About 0·21 of the whole light lies in the range 520-540$\mu\mu$, and about 0·017 of the energy between 410 and 760$\mu\mu$ lies within this range. The quantum at 530$\mu\mu$ has the value $3{\cdot}71 \times 10^{-12}$ erg. sec. This gives the result that 9840 quanta per sec. of green light are required to produce the sensation of a continuous point source. For a flash to be visible 1400 or 2600 quanta of green light are necessary, according to the observer. If the flash is red or violet, a much greater number of quanta will be required. In making the calculation we have neglected the absorption of light in the media of the eye, but this cannot affect the result seriously.

There is a striking result connected with the visibility of small sources: visibility requires the same quantity of light, no matter what is the angle subtended by the source, up to an angle of one or two degrees. This is known as Riccò's law of foveal vision. It might be supposed that there is some connexion between this law and the quantum. But the numerical values show that there is none.

Effect of Magnetic Field on Dielectrics.

IN a letter in the issue of NATURE for July 12, Prof. P. L. Burns states that the power factor of certain dielectrics is decreased when a constant magnetic field is superimposed on the dielectric which is being subjected to an alternating electric stress. One would expect that on the Debye dipole theory of polar molecules in a viscous medium the power factor would be changed by a magnetic field.

The motion of the electrical charges, or, if the molecule contained a magnetic moment, the motion of the magnetic field in a superimposed electrical or magnetic field, would give rise to a loss of energy. The force acting on the molecule would be of a nature similar to the frictional force due to the viscosity of the medium. The relaxation time is given approximately by $4\pi\eta r^3/KT$. These forces could be considered to increase the value of η and hence increase the relaxation time. This would tend to shift the peak of the power factor against frequency curve toward lower frequencies. Therefore, depending on which side of the peak one was measuring the power factor, the power factor would be either increased or decreased by the magnetic field.

It would be interesting to know on what materials Prof. Burns found his results. It seems clear that power loss in dielectrics cannot be completely explained on the Debye theory. Some work has been done here considering the double layer surrounding colloidal particles and its effect on the power factor. Possibly these experiments of Prof. Burns would make it possible to distinguish between the two mechanisms.

The Space-Group of Strychnine.

IN connexion with the recent work on strychnine described by Prof. R. Robinson in his recent Bakerian lecture, the results obtained from an X-ray investigation may prove of interest.

The substance forms extremely good crystals, for which I am very much indebted to Prof. Robinson.

Results:

Unit cell	$a = 11{\cdot}9_2$ A.					$c = 11{\cdot}3_0$ A.	
	Volume 1634 A³.						
Axial ratio	a	:	b	:	c		
	0·983	:	1	:	0·931		
	0·9827	:	1	:	0·9309	(Groth)	
No. of molecules	4						
Space group	Q_4	(Astbury and Yardley, *Phil. Trans.*, A, vol. 224; 1924).					

The dimensions of the cell, and the space group, are such that four molecules of the disc-shaped form suggested by Prof. Robinson can be fitted into the unit cell. Owing to the complicated nature of the molecule, and to the fact that it is composed of comparatively light atoms which have approximately equal scattering power for X-rays, it is impossible at this stage to make any further assumptions as to its structure.

Occurrence of Mannitol in Spike Disease of *Santalum album* (Linn.).

WHILE investigating the water soluble constituents of the spiked leaf of sandal, it was found that crystals of mannitol separated on slowly evaporating the extract after clarification with basic lead acetate. 2-3 per cent of the alcohol, calculated on the weight of the green material, has been found in all the samples so far examined (15), while in no case has it been detected in healthy samples. The significance of this fact at the present stage is difficult to understand, but it appears that mannitol is one of the metabolic products of the virus. Whether such characteristic products are formed during the course of other well-known virus diseases or not is a matter for future investigation, and workers in similar fields will, no doubt, be interested in this discovery.

The Existence of the Cellobiose Residue in Cellulose.

THE chemical evidence for the view that cellobiose is preformed in cellulose is considerably strengthened by some observations we have made on the acetolysis of trimethyl cellulose. Under mild conditions of treatment at low temperatures fully methylated cellulose suffers cleavage to give a diacetyl-hexamethyl cellobiose, which is readily transformed into crystalline heptamethyl β-methylcellobioside. The experimental conditions under which this derivative of cellobiose is isolated preclude its occurrence as a reversion product of the reaction. Moreover, the yield of the crystalline β-cellobioside is equal to that of cellobiose octa-acetate obtained by the direct acetolysis of cellulose.

Johann Kepler, 1571-1630.

THE great German astronomer and mathematician Johann Kepler, the tercentenary of whose death is being commemorated this year, was born at the little town of Wiel or Wielderstadt, not far from Stuttgart in Württemberg, on Dec. 27, 1571, and died at Ratisbon in Bavaria on Nov. 15, 1630, in his fifty-ninth year. A cenotaph to his memory was erected at Ratisbon in 1803, and commemoration celebrations will commence on Sept. 24 with an address before the memorial by Dr. von Dyck, of the Munich Technical High School.

Born at a time when his country was already torn by religious dissensions, Kepler lived to see it drenched with blood by one of the most disastrous of all wars. Altogether he lived under four Emperors, Maximilian II., Rudolph II., whose lack of capacity for government was in no way compensated for by his love of alchemy and astrology, Matthias II., anxious but unable to prevent the coming storm, and Ferdinand II., whose ingrained hatred of Protestantism led to a reign filled with persecution and strife. The Thirty Years' War had been in progress twelve years before Kepler died, but ere it had run its course the land had become a wilderness and in Kepler's native district of Württemberg it is said 58,000 families had disappeared, while the population had shrunk to one-sixth of its former numbers.

Save, however, that Kepler was a Protestant; that he once had to quit his chair on account of his religious views; that he became imperial mathematician to Rudolph; that he compiled the Rudolphine Tables, and that for many years he was dependent on the royal favour for his income, his life's work was little connected with the doings of Church or State. While princes and ecclesiastics schemed, quarrelled, and fought, Kepler steadily pursued his own course and by the exercise of his matchless intellect solved some of the problems which had baffled the greatest minds. Kepler's true contemporaries were such as Gilbert, Napier, Bacon, and Galileo rather than emperors and kings, and though students will long read of Wallenstein and of Gustavus Adolphus and pore over Schiller's famous history, Kepler's name is destined to be handed down to the remotest posterity.

If there was little in the character of the times favourable to scientific studies, neither was there in Kepler's parentage and environment anything conducive to the upbringing of a scholar. His parents, it is true, were of noble descent, but they were also in impoverished circumstances, a condition which perhaps had much to do with the unfortunate family differences. Kepler himself was a sickly seven-months' child and his boyhood was marked by serious illnesses. Yet for all that he was able to attend school at Adelberg and Maulbronn, and at the University of Tübingen in 1591 he gained his master's degree in theology. It was at Tübingen he also heard the German astronomer, Michael Maestlin (1550–1631), lecture on the theories of Copernicus. Theology by then had become of secondary importance to Kepler, and, at the age of twenty-three, through the tolerance of the Archduke of Austria, although a Protestant, he was made professor of mathematics at Gratz in catholic Styria, and it was there he began brooding "with the whole energy of his mind on the subject, inquiring pertinaciously why the number, the size and the motion of the planetary orbits were not other than they are". How he published his hastily conceived explanations; how he was advised by Tycho Brahe to obtain a solid foundation for his views from actual observations; how he met Tycho at Prague and through him was made imperial mathematician, has often been told.

Tycho only lived a year after meeting Kepler, but their association has left its mark on the history of astronomy, and it was Tycho's observations which provided the material for Kepler's researches. Of the thirty or more works published by Kepler, two stand out as epoch-making, his "Astronomia Nova", published in Prague in 1609, and his "Harmonia Mundi", published at Linz in 1619. It was in the former—published, it may be remarked, the year that Galileo first used the telescope—that Kepler enunciated his first two laws, that the planets describe ellipses round the sun with the sun at a focus of each ellipse and that a line drawn from a planet to the sun sweeps over equal areas in equal times, while it was in the second work he gave the world his third law, that the squares of the periodic times are proportional to the cubes of the mean distances of the planets from the sun.

On Kepler's many other works, his commentary on Vitellus, his book on Dioptrics, a copy of which Newton used as an undergraduate, his writings on logarithms and his Rudolphine Tables it is unnecessary to dwell. Neither is it necessary to follow him to Linz, to Sagen, to Rostock, or to recall the domestic afflictions which befell him or the miserable tale of his constant impecuniosity due to emperors whose performances did not keep pace with their promises. Through foul weather and fair alike, Kepler continued constant to the one aim, the advancement of natural knowledge, and in so doing left a great heritage to the world.

In personal appearance Kepler, as we know from his own words, was lank, lean, and spare, and that "for observations his eye was dull and for mechanical operations his hand was awkward". His delicacy of constitution, no less than his weak eyes, was sufficient to prevent him becoming a great observer. He was as remarkable for the exuberance of his imagination as for his powers of thought and his untiring industry. With these he joined an open-mindedness and candour that led him not only to record his wildest fancies but also to emblazon his greatest errors. A staunch Protestant, pinning his faith to the Confession of Augsburg, he was sincerely religious, but averse to controversies. In other directions he declared himself as "troublesome and choleric in politics and domestic matters", yet with all his frankness he was probably an easy

man to live with. His singular action when after the death of his first wife he sought another is one of the most humorous of matrimonial adventures. At his request his friends sought for a suitable companion. Eleven ladies with strangely diverse qualifications were passed in review, and of them, after much vacillation, Kepler chose Susannah Reutlinger, the daughter of a cabinetmaker. Of her he wrote that she had an education worth the largest dowry. "Her person and manners are suitable to mine—no pride, no extravagance. She can bear to work; she has a tolerable knowledge how to manage a family; middle aged, and of a disposition and capability to acquire what she still wants." For fifteen years Susannah shared Kepler's joys and sorrows and difficulties, and she bore him seven children.

In his work Kepler found the fullest satisfaction, and a discovery elated him as much as it did Davy. In Kepler there was none of the cold, passionless calm we associate with Cavendish. Like a Luther, he regarded himself as an instrument of the Almighty, and his studies were interspersed with prayer. He had once written a small treatise on the Divine Wisdom as shown in the Creation, and his subsequent works contain many passages of exaltation. When after seventeen years of searching he discovered the third of his laws his delight knew no bounds. "Nothing holds me", he said, "I will indulge in my sacred fury; I will triumph over mankind by the honest confession, that I have stolen the golden vases of the Egyptians, to build up a tabernacle for my God, far away from the confines of Egypt. If you forgive me, I rejoice; if you are angry, I can bear it. The die is cast; the book is written, to be read either now or by posterity—I care not which. It may well wait a century for a reader as God has waited six thousand years for an observer." Kepler's work, however, was appreciated immediately by his contemporaries, while of his discoveries the famous French physicist Arago once wrote: "Les lois de Kepler sont le fondement solide et inébranlable de l'astronomie moderne, la règle immuable et éternelle du déplacement des astres dans l'espace. La gloire de Kepler est écrite dans le ciel; les progrès de la science ne peuvent ni la diminuer ni l'obscurcir, et les planètes, par la succession toujours constante de leurs mouvements réguliers, la raconteront de siècle en siècle."

The Taxonomic Outlook in Zoology.*

By Dr. W. T. CALMAN, F.R.S.

THE anatomist, the physiologist, the field naturalist, the student of one or other of the innumerable specialisations of biological science, has always been inclined to regard with distaste, if not with contempt, the work of those whose business it is to denominate, classify, and catalogue the infinite variety of living things. The systematist is generally supposed to be a narrow specialist, concerned with the trivial and superficial distinctions between the members of some narrow group of organisms which he studies in the spirit of a stamp collector; happy when he can describe a new species, triumphant if he can find an excuse for giving a fresh name to an old one.

It would be idle to deny the truth that there is in these criticisms, just as it would be easy, although unprofitable, to point out that the substance of them might be directed against the practice of most other branches of research. The specialist, of whatever kind, has a tendency to mistake the means for the end, to become fascinated by technique, and to suffer from a myopia that blurs his vision of other fields than his own.

I think, however, that there are some signs of an increasing appreciation of the usefulness and even of the scientific value of taxonomy among the younger generation of zoologists. More particularly, those who are concerned with the applications of zoology to practical affairs are, for the most part, although not invariably, aware of the need for exact identification of the animals they deal with. They do not always realise the difficulties that may stand in the way of this identification. It is a common experience with us at the Natural History Museum to have some mangled fragments of an animal brought in by a practical man, who expects to be supplied with the name of it while he waits. I am afraid that he often goes away with a low opinion of our competence.

It may not be without interest, therefore, if I attempt, in the first place, to give some idea of how matters stand with this part of the systematist's task, the identification and description of the species of living animals.

When Linnæus published in 1758 the first volume of the tenth edition of his "Systema Naturæ", he named and described about 4370 species of animals. If we ask how many are known to-day, the diversity of answers we get is some indication of the confusion that exists. Some years ago, at the request of the late Sir Arthur Shipley, I endeavoured to get from my colleagues at the Museum estimates of the numbers of species in the various groups with which they were specially conversant. Some of the answers obtained were very interesting. With regard to mammals I was told "anything from 3000 to 20,000, according to the view you take as to what constitutes a species". For the most part, however, the authorities consulted were unwilling to suggest even an approximate figure, for a very different reason. They told me that great sections of the groups with which they were concerned were so imperfectly surveyed that it was quite impossible even to guess how many of the supposed species that had been described would survive reconsideration.

It may be worth while to consider for a little the

* From the [presi]dential address to Section D (Zoology) of the British Associa[tion] delivered at Bristol on Sept. 4.

second of the two obstacles thus indicated as standing in the way of obtaining a census of the known species of animals. In the days of Linnæus, it is likely that a very experienced zoologist might have been able to recognise at sight any one of the four thousand species of animals that were then known, and when the expansion of knowledge had made such a feat no longer possible, the specialist who confined his studies to one section of the animal kingdom could still aspire to a like familiarity with the species of his chosen group.

With this kind of knowledge it is literally true that, as has been said, a systematist recognises a new species by instinct and then proceeds to search for the characters that distinguish it. Some of the great zoologists who were still working in the British Museum when I entered it more than a quarter of a century ago, men like Albert Günther, Bowdler Sharpe, C. O. Waterhouse, and Edgar Smith, had actually an amazing personal familiarity with vast sections of the animal kingdom. They had studied and digested all that had been written on their subject, and, if they did not carry the whole of this knowledge in their memory, they could, without searching, put their hand at once on the volume that would help them. They had no need of 'keys' to help them to run down their species: indeed, they rather distrusted such aids, for they knew how easily they betray the heedless.

Specialists of this type there must always be, and we may be thankful for it. Nothing can altogether replace that instinctive perception of affinity that comes from lifelong study. It has often happened that men such as those I have named were able, when confronted with new and aberrant types of animals, to allot them at once to a place in classification which subsequent research served only to confirm. As time goes on, however, the extent of ground that can be covered in this fashion by the most industrious worker is rapidly diminishing. The torrent of publications catalogued in the "Zoological Record" increases year by year, and the specialist, if he is not to be overwhelmed by it, must not allow his curiosity to stray beyond the limits of a narrow corner of the field.

By far the greater part of this literature is written by specialists for specialists, and much of it is unintelligible to anyone else. From the time of Linnæus, however, there have not been wanting publications that have a different aim. We have monographs, synopses, revisions, of all sorts and sizes, attempting to render possible the identification of species without demanding a lifetime of study for each special group. The ideal for such monographs would be, I assume, that they should be intelligible to, and render possible the determination of species by, any properly trained zoologist, even without previous experience in dealing with the particular groups of which they treat.

The Zoological Department of the British Museum may fairly claim to have done more towards this re-editing of the "Systema Naturæ" than any other institution in the world. The long series of monographs, of which the true character is somewhat concealed under the official title of 'catalogues', is a monument to the learning and industry of the great zoologists who planned and executed them. Though they remain indispensable to all serious students of the different groups, however, they are now, for the most part, long out-of-date, and, vast as is their scope, they cover only a fraction of the animal kingdom.

In 1896 the German Zoological Society began the publication of "Das Tierreich", afterwards continued by the Prussian Academy, which was planned to give nothing less than a revision of all the species of living animals. Here again, however, after thirty-four years, only a small part of the ground has been covered and already the progress of research has rendered many of the earlier parts obsolete. Col. Stephenson tells me that Michaelsen's revision of the Oligochæta, published in this series in 1900, deals with exactly half the number of species enumerated by the same authority in 1928.

Apart from these attempts at comprehensive revision, we have, of course, numerous surveys of local faunas on a larger or smaller scale, besides monographs of restricted groups, but scarcely ever do these fit together without leaving gaps, geographical or systematic.

The number of described species of animals has been estimated at something in the neighbourhood of three-quarters of a million. It is not at all improbable that between a quarter and a third of that number would be suppressed as synonyms or put aside as *species inquirendæ* by careful monographers, and that in many groups the proportion would be far higher.

The prospect is not one that can be contemplated with any satisfaction. The successively expanding volumes of the "Zoological Record" give us a picture of systematic zoology being smothered under the products of its own activity. The confusion will grow steadily worse unless systematists come to realise that the mere description of new species is a far less important thing than the putting in order of those that are supposed to be already known, and until, on the other hand, zoologists in general cease to regard taxonomy as a kind of menial drudgery to be done for them by museum curators.

I have alluded to another obstacle to obtaining an enumeration of the animal kingdom, in the divergences of opinion as to what constitutes a species. I am not sure that these divergences are not sometimes over-estimated. I think that it will be found that in most orders of animals there exists a considerable body of species regarding the limits of which there is no serious difference of opinion among competent systematists; but alongside these we find in almost every order, in most families, and even in many genera, a 'difficult' residue in which the delimitation of specific groups sometimes seems to be little more than a matter of personal taste. Mr. G. C. Robson has recently brought together a great deal of information on

this subject in his book "The Species Problem", to which I would refer anyone who needs to be convinced how complex the problem really is. For our present purpose it is enough to take the empirical fact that the majority of animals can, with more or less trouble, be sorted into assemblages or kinds that we call species. We have seen how imperfect and confused is the present state of knowledge even as regards the mere description and identification of those kinds.

The business of the systematist, however, does not end with identification. Even identification requires some kind of classification, if it is only the classification of the dictionary. Since the time of Linnæus, or rather, since the time of John Ray, zoological systematists have believed in the existence of a natural system of classification which it was their business to discover; since Darwin it has seemed plain that this natural system must be, in some way, based upon phylogeny. It is now realised that the relation between the two is not always so simple and straightforward as it once appeared to be. Dr. F. A. Bather, in his presidential address to the Geological Society in 1927, discussed the historical and philosophical bases of biological classification. He concluded that "The whole of our System, from the great Phyla to the very unit cells, is riddled through and through with polyphyly and convergence", and that "Important though phylogeny is as a subject of study, it is not necessarily the most suitable basis of classification". I am not sure that I quite understand what is implied by the second of these statements, but I do not suppose that even Dr. Bather would be prepared to suggest a system of classification entirely divorced from phylogenetic considerations.

Forty years ago the reconstruction of the evolutionary history of the major divisions of the animal kingdom was almost universally regarded as the chief end of zoological research. To-day, except among palæontologists, one might almost say that the phylogenetic period in the history of zoology has come to an end. When one recalls the extravagances of its later developments, the derivation of vertebrates from arachnids and of echinoderms from cirripedes, one cannot be surprised that zoologists of the modern school take little interest in it. If we accept this attitude, it follows that problems of affinity and relationship are not worth worrying about. We are told, in so many words, that our business as systematists is identification, not classification; that what we have to do is merely to devise some kind of key or card-index that will enable animals to be quickly and easily sorted into species. So far as the really scientific branches of zoology are concerned, an artificial system of classification is as good as, and may even be better than, any other.

It is quite true that the categories of the physiologist, the ecologist, the geneticist, and so on, often cut across the dividing lines of the most natural classification we can devise, but both the divergences and the coincidences are worthy of closer consideration than they sometimes receive. If there is any truth in the theory of evolution, it is obvious that functions and habits have an evolutionary history behind them, but it is no less obvious that this history has not been independent of the history of the organisms that display them. The details of this history we shall never fully know, and even its broad outlines may perhaps always remain misty. A natural system of classification expressing even these broad outlines may prove to be an unattainable ideal, but each step towards it holds out the promise of usefulness in other and possibly remote fields of research.

A great deal of current work and still more of current speculation in zoology seems to me to suffer from this neglect of the taxonomic outlook. In the zoology of the later nineteenth century the comparative method was still the chief tool of morphology. The relative importance of structural characters was measured by the extent of their persistence through larger or smaller divisions of the animal kingdom. This point of view tends to be lost sight of with the increasing emphasis on the experimental method. The systematic zoologist, in listening to the exponents of the modern lines of research, is apt to be impressed by the little account that is taken of the vast variety of animal life. To say this, is not to underrate in any way the advances that have been made in these lines within the present century or the revolutionary changes they have made in our views on many fundamental questions. Physiology, for example, is to-day a vastly different science from what it was thirty years ago, partly because the physiological laboratory has a more varied fauna than it had then. Nevertheless, the zoologist, conscious of the unending diversity of structure and of habits among animals, sees the physiologist's results against a background of which the physiologist himself seems to be sometimes forgetful.

One hesitates to suppose that the students of heredity are really so forgetful of this background as they sometimes seem to be. No doubt intense specialisation is needed for intense research; but the Poet of the Breakfast Table, laughing gently at the narrow specialism of the Scarabee, can scarcely have foreseen the day when a university in his own country would have upon its teaching staff an officer named in the university calendar as a 'Drosophilist'.

It is possible, however, that the prevailing lack of interest in questions of phylogeny may have a deeper significance. Those departments of biology that are being most actively studied at the present day are preoccupied with the interplay of forces acting here and now. They ignore the impressions that time may have left on the material of their study. It is as though a crystallographer, studying a pseudomorph, should endeavour to explain its form in terms of its chemical composition and the forces governing the arrangement of its molecules, without taking account of its past history.

From ignoring anything, it is but a short step to denying its existence, and here, it seems, we have already arrived. In a lecture delivered in

London in the early part of last year by that very distinguished experimental biologist Dr. Hans Przibram, he suggested that we might have to consider the possibility that every species of metazoan has developed independently of all the others from a distinct species of protozoan. The same view was set forth by him in a lecture delivered in Paris on the theory of apogenesis (*Rev. Gen. Sci.*, **11**, No. 10, May 31, 1929, p. 293). As the English lecture has not been published, I will translate as closely as I can from the French one. "I do not think it likely", he says, "that a single substance can have given rise to a general phylogenetic tree according to the classical diagram representing the affinities of species and their distribution in space and time. All the facts would be explained more easily by supposing that there existed, at the beginning, many organised substances developing side by side into species, each of the latter passing through stages more and more advanced without actual relationship of descent between the different species."

Many authors have believed in a multiplicity of the primordial forms of life, but few have suggested an independent origin for grades lower than the main phyla. Przibram, with strict logic, has carried the same reasoning down to the individual species. Most biologists with whom I have discussed the matter refuse to take his suggestion seriously. This, I venture to think, is a mistake. Przibram has simply carried to their inevitable conclusion certain lines of thought that we meet with everywhere in current biological literature; that conclusion is either one of the most significant results of recent biology or it is the *reductio ad absurdum* of much contemporary work.

Geneticists have made us familiar with the doctrine of the inalterability of the gene, with its corollary of evolution by loss of factors, which, by the way, seems to differ little from Przibram's apogenesis. The experimentalists have proved (if it wanted proving) the plasticity of the phenotype, as, for example, when Przibram himself shows that the length of a rat's tail is a function of the temperature to which the individual and its immediate progenitors have been exposed. As for the inheritance of impressed modifications, the more unequivocal the experiments devised to demonstrate its reality the more clearly do they show it to be of so fugitive a kind as to have no significance in evolution. Palæontologists, as Dr. Bather has told us, have proved beyond the possibility of doubt the occurrence of parallel and even of convergent evolution, without telling us where we are to stop in applying the principle. Many supposed examples of adaptation fail to stand closer scrutiny, and therefore the whole idea of adaptation is declared to be a subjective illusion. All these results at any rate place no obstacles in the way of Prof. Przibram's suggestion.

It is to be noted that although the theory of apogenesis is called a theory of evolution, it does not deal at all with evolution as that word was used by Darwin. It has nothing to say on the origin of species. On this question it is no more than a doctrine of special creation at one remove. It has no light to throw on classification. If we are to abandon belief in community of descent, the whole architecture of the "Systema Naturæ" becomes meaningless.

Prof. Przibram claims that "All the facts would be explained more easily" upon his hypothesis, but there is one point on which he speaks with a hesitant voice, and it seems to me a very significant exception. "We cannot decide", he says, "whether the differing though related species that inhabit islands or isolated territories are descended from a common source or result from the accidental separation of species which formerly occupied the region together."

Let me recall the opening words of the "Origin of Species". "When on board H.M.S. 'Beagle' as naturalist, I was much struck with certain facts in the distribution of the organic beings inhabiting South America, and in the geological relations of the present to the past inhabitants of that continent." So Przibram ends where Darwin began. The geographical and geological distribution of organisms, which for the one are merely the negligible residue of unexplained facts, were for the other the very heart and core of the problem he set himself to consider.

It is worth remembering that among Darwin's other qualifications as an interpreter of Nature, he was an experienced taxonomist, and before he wrote "The Origin of Species" he had produced one of the finest systematic works ever written in his "Monograph of the Cirripedia". Those of us who were present at the memorable Darwin-Wallace celebration of the Linnean Society in 1908 remember how the veteran Alfred Russel Wallace discussed "the curious series of correspondences both in mind and in environment" which led Darwin and himself, alone among their contemporaries, "to reach identically the same theory", and how he gave the first place to the fact that both he and Darwin began by collecting beetles and thus acquired "that intense interest in the mere variety of living things" which led them to speculate upon the 'why' and the 'how' of "this overwhelming and, at first sight, purposeless wealth of specific forms among the very humblest forms of life". It might be worth while to inquire whether a training that proved useful to Darwin and to Wallace would not be of some value to students of zoology even at the present day.

The experimental method has answered many questions and it will answer many more, but there are some questions, and these well worth the asking, to which experiment will never find an answer. No one will maintain that taxonomy by itself will answer them, but it will often suggest where the answer is to be sought for, and it will provide a point of view from which both questions and answers will be seen in a true perspective.

Finally, I would recall a remark once made in my hearing by a wise old naturalist, the late Dr. David Sharp. Someone had been remarking on the

decline of systematic zoology and predicting the extinction of systematic zoologists. Dr. Sharp replied, in effect, "I have seen many passing fashions in zoology, many departments of research becoming popular and then falling into neglect; the one branch that will never fail to attract is the systematic one. The æsthetic satisfaction to be derived from contemplating the mere variety of animal forms, and from tracing the order that runs through all its diversity, appeals to a very deep instinct in human nature. There will always be systematic zoologists."

Obituary.

PROF. H. W. WILEY.

IN Harvey Washington Wiley, who died on June 30, we lose a man who was a great Uesanian warrior in the cause of pure food, a man of imperious character, officially a perfervid Puritan idealist and extremist, yet in the society of friends the perfect Yorick, "a fellow of infinite jest, of most excellent fancy". As first administrator of the American Food and Drugs Law, his own beloved child, he was nothing short of an all's-fair-in-love-and-war man: perforce, in fact, he had to adjust his methods of attack to the times and to those of his foes, as he was severely up against trade interests. He trod heavily upon not a few corns and it is clear that, occasionally, his pendulum swung beyond the limits of scientific reason; still, the end was one to justify almost any means. He had courage and, in large measure, won, as he definitely established a sound public opinion.

I first met Wiley in 1903, at his most active period, at a gathering of Agricultural Experiment Station workers, in Minneapolis, at which I was present as Lawes lecturer. He was the life and soul of a large meeting; ever full of resource. Thus, on one excursion, in a dry town on a very hot day, displaying a surprising geographical instinct, he took some of us poor sufferers to a pharmacy and tendered a prescription on our behalf: the medicine we got passed all the Brer Rabbit tests for good ale and no doubt saved our lives. A few years later he and I forgathered at Washington, in the Cosmos Club, an institution the worth of which will be known to many. We met one afternoon in the main square, to go out to the Country Club. He was carrying a parcel and there was a suggestive bulge at his hip. We were to pass the county border, into an arid region. The parcel and that bulge were of no slight aid to our evening's pleasant intercourse. There is an immoral to this tale. At the time of his retirement, late in life, he passed under petticoat rule, to become thereafter an exemplar of dryness. The injury done to him by his previous depravity—at least so his friends claimed—was made obvious by the arrival, without undue delay, of two healthy boys. Several months ago, hearing that he was very ill, I wrote to cheer him, suggesting that he set an example by repenting of his later sin. This amused him, I was told. The reply, bearing his signature, gave too much advice for the good of my soul to be his. I could only write back that John Barleycorn had not done much obvious harm to either of us. My old friend became in fact a first-class humbug in the matter of drink: probably he was never a man of really balanced, scientific judgment. We have to hold such men very much in mind, however, in taking stock of the States: too few realise how rigid the American outlook often is.

Only recently, the *Times* told us, an American Senator wrote to our Ambassador in Washington to protest against the exercise of his right to take liquor into the Embassy, suggesting that such action was likely to have the most serious effect upon our international relations. Do Americans recognise how entirely they are cutting us off from rational intercourse with them? We welcome them here in crowds and they do not seem to return habitual drunkards. Few of us go from this side as travellers —we only visit the States when compelled, either on business or when imported to join in colloid worship at Cornell or some similar academic frivolity. Few Uesanians understand how impossible it now is for us to risk travelling in their country—the danger of their soft drinks. Yet it is one that is full of beauty and interest, as I can vouch; the only difficulty is that there is so much of it. Whatever it be, it is a land in which, at times, every pore of you aches for beer; one where the hart ever pants for the cooling Milwaukee stream.

Straining at the gnat ethanol, to-day, Americans swallow the camel caffeine in canfuls: however, a missionary from here is now in Canada who will disabuse them (of course piously, on week-days) of this delight. As a matter of fact, Wiley, in 1912, warned the American public against the danger of too much caffeine. He was often here and always amusing. Describing once the activities of his Department, he told how advice was given which led to the need for water in one of the arid regions of Texas being overcome: this was done by growing onions between rows of potatoes; the eyes of the potatoes watered so much that artificial irrigation became unnecessary.

It matters little where a man like Wiley came from. *Pro forma*, let it be told that he was born in Indiana on October 10, 1844. In 1863 he went to College; in 1868 he began to study medicine, graduating M.D. from the Indiana Medical College in 1871. Probably medical education at that time was no great shakes. He then had a year in the Lawrence school at Harvard; became professor of chemistry in Butler College, in 1873; from 1874 to 1883 he was professor of chemistry at the Agricultural College, Purdue, Indiana, spending a year in Germany during this period. State chemist of Indiana in 1881, he was made chief of the Division of Chemistry in the U.S. Department of Chemistry in 1883. He was president of the American Chemical Society in 1893–94. In 1901 he was pro-

moted chief of the Bureau of Chemistry. Then it was that food reform became his master passion.

Wiley resigned in 1912, after great provocation. The Food and Drugs Law had been enacted after half a century of effort and discussion. The measure came into operation in January 1907. Almost at once, he has told us, he discovered that his point of view was fundamentally different from that of his superiors. During six years the feeling grew that the differences were irreconcilable and he became conscious of an environment which was essentially inhospitable. The fundamental principles of the Bill, as they appeared to him, one by one, were paralysed and discredited. It is easy to imagine what happened: the thorn he must have been in the side of the provision trade and the attempts that will have been made to unseat him. Convinced that he could work more fruitfully by rallying public opinion to the support of the cause he had so much at heart than by exercising the limited activity left to him in his official position, he resigned. On retiring into private life, he interested himself in his farm and became a diffuse, popular writer of food propaganda.

We have, I think, to quarrel severely with Wiley's extreme attitude towards preservatives in food. His view was that there should be no addition of any kind made to food. As the primrose to Peter Bell, every food spade, to the public, was to be a spade absolute, nothing more. His most celebrated work is the inquiry he undertook, with a set of young men as subjects, to ascertain the effect of preservatives, especially boric acid: the results were recorded in a very lengthy report of about 2000 pages. Grave exception has been taken to this work. He was probably not qualified, either as chemist or biologist, to undertake such an inquiry: he was far too much a victim of preconceived opinion and not sufficiently trained either as observer or as logician. He would have excluded every preservative. Owing, however, to Ira Remsen's intervention, whose higher scientific standing prevailed, benzoic acid was allowed. Wiley, I believe, managed later to persuade the President to subvert this decision.

As is well known, within recent years, our Ministry of Health, which is a hive of idealisms, has followed the American suit. No scientific proof has yet been given that, used as an antiseptic, boric acid does harm when added in the small amounts needed to preserve even so perishable an article as cream. The officials of the Ministry are no more competent than Wiley was to settle such an issue. The decision was taken by a Departmental Committee on idealistic grounds. As a result, the cream industry is severely dislocated, if not destroyed. The public have full right to complain, the more as sulphur dioxide is still allowed in some beverages: its evil effect is well known to many who go to public dinners. I hold no brief; my mind is open. I know what the danger is in lead works, when there is real exposure. I also know the great boric acid works in Tuscany; these reek of the acid in every direction—yet the work-people are all healthy. If only in justice to Wiley's memory, we ought, without delay, to study the problem afresh scientifically, with complete thoroughness and detachment, so that we may either justify or cancel his finding. It is farcical for us to hold the cake of science and not eat it. We can't afford such extravagance to-day.

HENRY E. ARMSTRONG.

MRS. ALBERT HOWARD.

A SEVERE blow has been dealt to the progress of science in India through the death at the age of fifty-three years of Mrs. Albert Howard, which took place at Geneva on Aug. 18 last. Miss G. L. C. Matthaei entered Newnham College, Cambridge, in 1895 and secured the double distinction of a first class in both parts of the Natural Science Tripos. Thereafter she continued to reside at Cambridge, being elected a fellow, and later an associate, of her College. She was fortunate at that time in coming under the powerful influences of Miss Ida Freund and Dr. F. F. Blackman. Her work in association with the latter developed in her a capacity for patient pursuit of the elusive in research which was so marked a characteristic of her work to the last. That early work is to be found in the *Philosophical Transactions* of the Royal Society, and has found a permanent niche in the literature on vegetable assimilation.

From 1905, when she married Mr. Albert Howard, the scene of her activities shifted to India. With that marriage commenced a comradeship which, if not unique in the annals of science, is at least unique in that it received official recognition from the Government of India, for, in 1910, she was appointed personal assistant to her husband and, in 1913, Second Imperial Economic Botanist. She was also awarded, by H.M. the King, the Kaisar-i-Hind medal of the First Class.

It is not possible, even for one who has had the privilege of sharing in part of the labours of the Howards in India, to apportion merit between the two comrades. Their work stands, and is best left, as a joint record of their devotion to each other and to India. But Mrs. Howard's association with Pusa introduced a definite economic trend, absent from her earlier work but becoming more and more marked with time. In 1905 the Agricultural Department in India was but recently reorganised and the impetus given by the rediscovery of Mendel's work was still fresh. The earlier papers are tinged by these facts and many plant breeding problems in this new field were brought to solution by these new methods. But even at this period the economic aspect was not neglected, as the 'Pusa wheats', already entering into general cultivation, and now covering more than three million acres, witness. This earlier work culminated in the monograph on "Wheat in India", and thereafter an ever-widening field opened out. The logic of a position in a country where rotations are habitually practised cannot be denied; the whole field of crop production and the methods of applying science thereto becomes the centre of investigation. This urge to a wider field of

investigation is traceable through the large series of publications which have appeared. It is an urge which found its consummation in the foundation of the Institute of Plant Industry at Indore, where the last six years of her life's work have been conducted.

The same widening outlook found an outlet in the first proposals for the founding of an Indian Science Congress. In that movement Mrs. Howard took a deep personal interest and she presided over both the Botanical and Agricultural Sections. It is not possible to estimate the material benefit of her work to India—undoubtedly it has been great; but the greater loss is that which arises from the balanced judgment, on both scientific and practical problems, which she was ever ready to place at the disposal of all who sought it.

PROF. JEAN BRUNHÉS.

JEAN BRUNHÉS, the French geographer, who died at Boulogne-sur-Seine on Aug. 25 at the age of sixty-one years, was one of the leading exponents of human geography of his time. By his teaching and published works he did much to put the subject on a sound scientific basis, and to lift it from the narrow lines of geographical determinism into which it tended to fall some years ago.

Brunhés was born at Toulouse and studied law at the university there before turning to science at the École Normale. His first work was on the geographical conditions of irrigation in Spain and Northern Africa. This was published in 1902 and showed a grasp of geographical correlations and a width of outlook. Much of his later work was done during the sixteen years when he held the chair of geography in the University of Fribourg, to which he was the first appointment.

In 1910 Brunhés published his "Géographie Humaine", which immediately became a standard work and has remained so to this day. It was afterwards expanded into a much larger work, and it also appeared, with some changes, in an English edition. Brunhés was also responsible for the geographical chapters in Gabriel Hanotaux's great history of France. These constitute a whole volume entitled "Géographie humaine de la France". A third important work was his "Géographie de l'histoire". According to the *Times*, he was engaged at the time of his death on a history of races. Brunhés was elected a member of the Institut de France in 1927.

WE regret to announce the following deaths:

Mr. Walter Deane, a past president of the New England Botanical Club, who was known for his work on the flora of north-eastern North America, on July 30, aged eighty-two years.

Prof. Cornelius Doelter, emeritus professor of mineralogy in the University of Vienna, and author of works on chemical mineralogy and related topics, on Aug. 8, aged seventy-nine years.

Mr. Henry W. Henshaw, formerly chief of the Biological Survey of the U.S. Department of Agriculture, and author of "Birds of the Hawaiian Islands," on Aug. 1, aged eighty years.

Dr. Wyatt W. Randall, formerly chief of the Maryland Department of Health, and president in 1926 of the Association of Official Agricultural Chemists, on July 22, aged sixty-three years.

Mr. J. W. Wilson, from 1892 until 1908 president of the Society of Engineers and co-founder with his father of the Crystal Palace School of Engineering in 1872, on Sept. 3, aged seventy-eight years.

News and Views.

IN our last issue (NATURE, Sept. 13, p. 391) we referred to the measures which are being taken or are under consideration by the Commonwealth Government of Australia to ameliorate conditions among the aborigines. Of the suggestions which have been made, the most important is undoubtedly that which recommends that the aborigines as a whole should come under the control of the Commonwealth Government. It involves many difficulties and would entail numerous adjustments as between the Commonwealth and State authorities; the obstacles, however, should not be insuperable, and the advantages which would accrue are too great to be lost without determined effort. Not the least of these would be that continuity and uniformity in policy could be secured by one authority dealing with the aboriginal question as a whole; and further, a wider and more effective public opinion would be brought into play when any question affecting policy or any specific measure was under consideration. All competent observers are agreed that in present conditions the extinction of the aborigines is a matter of only a comparatively brief period. With the lamentable example of the extinct Tasmanians to point the moral, no measure, however difficult of achievement, should be left untried to avert a similar fate from the Australian tribes, in some cases, unfortunately, already reduced to the merest fragment.

THE question of the aborigines is more than a domestic matter which concerns Australia alone. Apart from humanitarian considerations, the question touches a wide circle of interests in the world of science. At the recent Bristol meeting of the British Association a resolution submitted to the Council pointed out that the Australian aborigines are now among the most valuable peoples available for scientific study, and offer opportunities of unequalled importance for research and future investigation in the early history of mankind. The resolution, while recognising the value of the measures now proposed by the Commonwealth Government, went on to ask the Council to urge upon that Government the need for anthropological training for officials entrusted with the administration of the affairs of the aborigines and the adoption of every means to prevent their extinction and the further disintegration of native society. Notwithstanding the economic and financial

difficulties in which Australia is at present involved, the time is favourable to the initiation of an enlightened policy. Under the Anthropological Research Fund of the National Research Council, now well on its feet after three years' work, the Government has a body of expert workers who are making an intensive study of the aborigines ; in the existing system of Protectors of the Aborigines it has the machinery through which, given the requisite anthropological training, the results of that intensive study can be brought to bear upon the problems of administration ; and lastly, in Papua and the mandated territory of New Guinea, the administrative officers of which receive an anthropological training in the University of Sydney, it has the example and the experience necessary for guidance in dealing with the problems of training and organisation.

EXCAVATIONS at Kent's Cavern, Torquay, have been continued during the past winter from October to May by the joint Committee of the British Association and the Torquay Natural History Society. According to the report of the Committee, the trench begun last year has been carried to a length of 60 feet and a depth of 7 feet below the upper stalagmite floor, bed rock being reached near the entrance of the Wolf's Cave. Finds, probably not in their original position, included a quartzite pebble of Budleigh Salterton Pebble Bed type, which had been used as a hammerstone, three flints showing signs of use, and an interesting bone implement shaped to a sharp and much used point. These finds were in the 'Sloping Chamber'. The fauna, all of late Pleistocene type, included horse, still predominating over hyena, rhinoceros, stag, mammoth, *C. Megaceros*, bear, bos, and wolf in the numerical order named. The deposit is of mixed ages, the middle crystalline stalagmite floor being absent. In deepening the Bear Den the base of the concrete breccia was reached, revealing a fine silt below apparently identical with the silt at the base of the deposit in the 'Gallery'.

A REPORT on Educational and Documentary Films prepared by a British Association committee, of which Sir Richard Gregory is chairman and Mr. J. L. Holland is secretary, was presented to the Education Section at the recent Bristol meeting. The committee has restricted itself to the consideration of four matters and makes suggestions on cinematograph films, cinematograph apparatus, illumination and eyestrain, and structural conditions. The most important recommendation is that for classroom use the film should be non-inflammable, as is usually the case with films of 16 mm. width. The difference between the nitrate base film and the acetate (or non-flam) film is, however, not so great in the sub-standard size as when the film is of a width of 35 mm. It is pointed out that the 16 mm. film gives excellent results in classrooms not exceeding a seating capacity of 80, and the limit is, or will be, reached in lecture rooms for 120–150. Recommendations are made as to the size of screen suitable for use with this film and the structural conditions desirable when the projector is installed. In an appendix a specification is given of a 16 mm. projector.

WHAT does not appear in the report is the evidence on which the selection of a 16 mm. film is based, as against either larger or smaller sizes, unless it is contained in the statement that "there is a large selection of reliable apparatus for producing such films made by firms of repute". This, of course, is a condition to be taken into account, but when there are only about three hundred schools in Great Britain with apparatus of any kind and probably not half a dozen where it is used in the classroom for teaching purposes, as distinct from school halls for general education purposes, it would be worth while to undertake experiments to determine the ideal size, say, for the classroom. If that size could not be obtained, then it would be time to fall back on the 16 mm. On the face of it, the statement that the 16 mm. film is suitable for classrooms with eighty seats suggests that it is at least unnecessarily large for classrooms of thirty or even sixty, the maximum class number, soon to be done away with. Further, for anything from 30 per cent to 90 per cent of the time a film is used in the classroom, again in distinction to the hall, it is standing still, and in the case of the 16 mm. this has to be accompanied by a diminution of the light or the film will scorch. As the 9 mm. is somewhat too small, it may be suggested that the ideal size is somewhere about 11 mm. or 12 mm.

THE importance of accurate survey as a basis for the utilisation of land in our African colonies was emphasised in the Hilton Young Commission Report. In the *Journal of the African Society* for July, there is printed in full a recent lecture to the Society by Col. H. L. Crosthwait, in which he advocates the use of aerial survey in east and central African territories. Ordinary ground survey in a large colony would entail many years of work and very considerable expense before results of value were available. Col. Crosthwait points out that aerial survey would not only be three or four times as quick, but would also give a far greater amount of information about the economic resources of the country. This was shown in the recent survey of the Zambezi region, where reliable data were obtained regarding the geological structure, the state of the rivers, forestry, and other matters. It must also be remembered that aerial methods overcome many difficulties in swampy, heavily forested, or unhealthy country. Again, location surveys for railways and roads can be carried out much more rapidly by means of air survey than would be possible by the older methods. In a subsequent discussion on the paper, Sir Humphrey Leggett pointed out how much the administrative work of district and provincial commissioners would be facilitated by adequate maps. Col. Crosthwait does not advocate that the aerial surveys should be undertaken by the local governments themselves, but gave reasons why it would be less expensive and give quicker results to utilise private enterprise in the work.

THE programme of the ceremonies by which the Royal Geographical Society will celebrate its centenary on Oct. 21 next and the two succeeding days has now been issued. All the principal geographical

societies and institutions of the world have been invited to send delegates to these celebrations and a very large number have responded. Addresses of congratulation presented by these delegates will be received by H.R.H. the Duke of York, representing His Majesty the King, who is Patron of the Society, at the inaugural meeting at 3 P.M. on Oct. 21, when the Duke will also declare the new Hall, Library, and other buildings open for the use of the Society. The centenary meeting will be held in the newly opened hall at 8.30 P.M. on the same evening, when a series of addresses on the history of the Society will be given by the president and others. On the following evening the president, council, and fellows will entertain the delegates and a large number of official guests at a reception at 9 P.M. in the Society's House in Kensington Gore. The centenary dinner of the Society will be held on the evening of Oct. 23 at the Connaught Rooms, when H.R.H. the Prince of Wales, Vice-Patron of the Society, will preside. The programme announces also a series of communications from British and foreign geographers on the topics of the habitable globe and incidents in the history of exploration, to be presented at meetings on the morning of Oct. 22 and the morning and afternoon of Oct. 23.

THE determination of the permissible practical load an electric motor or dynamo can carry, that is, the determination of the power at which it should be rated, is a practical problem of considerable difficulty. The temperatures of the various parts of a machine must not exceed the limits given in the specification after it has been running on load for many hours and has attained its steady thermal state. Owing to the long time taken before the temperatures of the various parts of a machine reach their steady values, many attempts have been made to devise methods of predicting the final values by taking observations over a brief period of time. Could this be done, substantial economies could be effected in manufacturing works. The theoretical methods attempted generally proceed on the assumption that the heat convected away depends on the square root of the velocity of the rotating part and is proportional to the difference in temperature between the conductors and the surrounding medium. The loss by radiation, being much smaller, is generally neglected. Practical tests have also been made on model machines but hitherto no satisfactory methods of shortening the time of heating tests have been devised. In the *Journal of the Institution of Electrical Engineers* for July, two papers by Dr. E. Hughes describe the results of heating tests on actual machines. He varies the losses and the speeds, and his results show that the conclusions arrived at by experiments on models must be accepted with caution. The machines were tested both when 'totally enclosed' and when cooled by an induced draught. Several empirical formulæ are given, one of which enables the effect of speed to be allowed for when estimating the temperature rise.

A VERY novel use of refrigerating machinery for the salvage of ships is described by D. Mettler in the April–June issue of the *Escher Wyss News*, a journal published quarterly by the well-known engineering firm of Escher, Wyss and Co. of Zurich. Some years ago a Berlin engineer, W. Kiwull, devised a method of sealing a leak on a ship by forming a coating of ice over the rent in the metal hull. In northern seaports in winter time it is quite customary to see the hulls of ships all iced over, and this apparently suggested the idea to him. A company was formed and plans for a test plant were made and elaborated by Messrs. Escher, Wyss and Co. The test plant was to have a gross refrigerating capacity of 120,000 British thermal units per hour, and the power consumption was to be 25 horse power. The specification stated that the plant was to be erected and worked at a depth of between 10 ft. and 15 ft. below the level of the lake of Zurich. It was then to be worked for a fortnight without a hitch, maintaining its guaranteed output continuously. The refrigerating plant was contained in a water- and air-tight iron casing, the electric connecting cables and the connecting branches for the evaporating apparatus coming through. Under these trying conditions, the plant operated at full load continuously for 336 hours, that is, fourteen days and nights. A careful examination showed that it had not suffered the least injury. Many thousands of readings were taken during the tests, and the results show that the mimimum guaranteed output had been largely exceeded. From time to time the ice formation on the evaporative tubes was checked by divers. Ammonia vapour was employed and full technical descriptions are given in the journal of the compressing plant.

THE Report of the Carnegie Institution of Washington for 1929 is noteworthy, apart from its indications of progress in research, for the inclusion of a series of addresses delivered at special meetings at Cold Spring Harbor and on the research ship *Carnegie*, to celebrate the completion of twenty-five years' investigation in the biological and physical sciences. In the course of one of these addresses, Prof. E. G. Conklin summarised the progress of biology as one of four great eras. The first was the era of exploration and classification, when emphasis was placed upon differences amongst species and greater groups, and botany, zoology, and physiology were regarded as distinct and independent sciences. Then came the era of comparative anatomy, embryology, and physiology, when emphasis was placed on resemblances rather than on differences, when botany and zoology were seen to have much in common, though morphology and physiology remained independent. The third era was marked by generalisation and speculation regarding evolution, heredity, and variation, when family trees sprouted like weeds, and hypotheses were erected upon foundations of sand. The last and, according to Conklin, the present era, is one of experiment, of both analysis and synthesis, of a union of morphology and physiology. But we should be inclined to go further than Conklin and say that since there is no certainty that the experimental method, which necessarily interferes with the natural habits of animals, is final in its decisions, an old method in much improved guise is developing alongside the experimental—the close, continuous, and

detailed observation of the habits of creatures in their own environment.

PUBLICATION of scientific books is on the increase. The same may be said of books in every department of literature—a curious commentary on trade depression and the reduced spending power of the nation. The increases are far from being insignificant. Comparing the numbers published in the first half of 1930 with those of the corresponding period of last year (from the tables in the *Publisher and Bookseller* of July 4), we find that, with the exception of poetry, publication in every branch of literature has increased by 20 per cent or more, and following 'essays and belles-lettres' with an enormous increase of 108 per cent, come scientific or technical books with 86 per cent, the actual numbers in these two cases being 115–239 and 124–231. Medical books are grouped separately and here the numbers for last year and this year are 195–246, an increase of 26 per cent. The increase in numbers, which over all the list amounts to 40·45 per cent, is spread over works at almost every price, but the indication is that the average price tends to rise. Leaving out three exceptionally expensive books (priced at £70), it would appear that this year the average price stands at 7*s*. 5½*d*., against 6*s*. 9½*d*. in 1929. The total number of books of all sorts published in the first half of 1930 was 8017, an average of 44 a day, including Sundays. Where do they all find readers ?

THE serious decline in the numbers of the wild fur-bearing animals of California is indicated in *California Fish and Game* for April (p. 164), where a computation has been made of the numbers of skins taken under the trappers' licence law. The grand total of skins for the season 1928–29 stood at 103,508, including 39,407 skunk and 10,758 racoon, against 167,202 in 1927–28. In spite of higher average prices, the value fell in these two seasons from 468,960 dollars in 1927–28 to 280,309 in 1928–29. Some of the creatures concerned seem to be approaching the danger zone of extinction: twenty-nine 'fishers' were taken two years ago, but in the past season only seven, and the wolverine no longer makes an appearance in the list.

THE second number of the *Hong Kong Naturalist* (May 1930) improves even upon the high standard of the first, but as we suggested in noticing the earlier part, the editors have already found that many of their readers demand a larger proportion of simple and popular articles. This is a natural wish, and since it is desirable that the magazine should foster an interest in Nature, as well as constitute itself a guide to the details of fauna and flora in the region, the editors have wisely interspersed amongst the more technical papers, such as those on the orchids and the birds of Hong Kong and the fishes of China, articles of more general appeal on a wide variety of Nature topics.

THE Czechoslovak Ministry of Agriculture, acting in consultation with the chief official, public, and other bodies concerned with land improvement, drainage, civil engineering, etc., has started the preliminary arrangements for holding a land improvement exhibition in 1931. The exhibition will form part of the annual exhibition of the Agricultural League and will take place during the international agricultural congress at the end of May and the beginning of June in Prague. The exhibition will represent fully the activities of the various schools, institutions, public offices, and other bodies concerned with land improvement. It will be supplemented by meetings and discussions, as well as by visits to inspect work in progress, etc. Further information may be obtained from the Agricultural League, Prague.

REFERENCE was made in NATURE recently to the first report of the Bureau of Contraceptive Advice, Baltimore. A second report, covering the period of about a year ending Sept. 26, 1929, has been issued by Prof. Raymond Pearl. Advice has been given to 232 patients, compared with 168 during the first year, and an increasing number of physicians make use of the clinic. The Bureau has been in operation too short a time to make any definite report on the effectiveness of the advice given on contraceptive methods, but a wealth of material for the statistical study of various medical and biological problems has been collected. The largest individual number of pregnancies observed among the 400 women who have attended the Bureau since its inception is 22, and the largest number of children born to one mother is 15 ; this figure occurred three times.

THE Right Hon. the Viscount Chelmsford will open the new building for the Mining Department of the University of Leeds on Sept. 30 next. The building, forming the first portion of the University's scheme of construction, stands facing Woodhouse Lane at the north of the main site of the University.

THE following appointments in the Colonial Agricultural Service have recently been made by the Secretary of State for the Colonies : Mr. R. M. Nattrass, to be mycologist, Cyprus ; Mr. J. B. G. Savory, to be superintendent of agriculture, Nigeria ; and Mr. T. R. Stodart, to be dairy instructor, Palestine.

FATHER H. V. GILL, Rathfarnham Castle, Co. Dublin, commenting on the correspondence in NATURE of Sept. 6, p. 351, reminds us that an English translation of Boscovich's "Theoria Philosophiæ Naturalis" by Mr. J. M. Child was published in 1922 by the Open Court Publishing Co., and a review appeared in NATURE of Dec. 30, 1922, p. 870. In this work Boscovich gives his views on the properties of matter and in one of the Supplements he goes so far towards the theory of relativity as to affirm the inconstancy of length of a measuring rod moved about in space. An article, entitled "A Jesuit Pioneer of Relativity", including quotations from Boscovich's work, appeared in the issue for July 1926 of the *Dublin Review*.

REFERRING to Dr. Dirac's suggestion with regard to 'negative energy', in his British Association paper on the proton, Sir Philip Hartog writes to recall Osborne Reynolds's theory that "matter represents negative mass" ("Sub-mechanics of the Universe", 1903, p. 3).

The theory was originally put forward, with experimental illustrations, in 1902, in his Rede lecture "On an Inversion of Ideas as to the Structure of the Universe". It is worth while supplementing this reminder by mentioning that in a letter in NATURE of Aug. 18, 1898, Sir Arthur Schuster suggested that potential or negative matter might exist, and in a further letter in the issue of Oct. 27 he directed attention to papers by Prof. Karl Pearson and A. Föppl on the same subject.

ARRANGEMENTS have been made for lectures during the forthcoming winter by Mr. H. V. Garner, the guide demonstrator, and other members of the staff of the Rothamsted Experimental Station, Harpenden, to chambers of agriculture and horticulture, farmers' clubs, farm workers' associations, agricultural societies, etc., on the Rothamsted experiments. No fee is charged for the lecturers' services, but any association engaging them would be expected to defray their travelling and hotel expenses, and to make such arrangements for the lectures as may be necessary. All communications regarding lectures should be addressed to the Secretary, Rothamsted Experimental Station, Harpenden, Herts.

DETAILS of a course of lectures on modern methods of analytical chemistry to be given during the forthcoming session have been received from the Principal of the Hackney Institute (London County Council). These lectures cover a wide field, including gravimetric, volumetric, optical, electrical, gasometric, micro and biological methods. Owing to the rapid growth of organic and physical chemistry, the time left for the study of analytical chemistry is a diminishing quantity, and the graduate, possibly with a good honours degree, taking up a position in a laboratory, soon finds that there is a large gap between his academic knowledge and the requirements of practice. Such a course as that mentioned above, if accompanied by sufficient laboratory work, should help to fill this gap. The teaching of analytical chemistry in Great Britain is still far behind that given in the United States and Germany.

A JOINT committee of the Association of Special Libraries and Information Bureaux (Sir Frederic Nathan and Lieut.-Col. L. Newcombe, National Central Library) and the British Society for International Bibliography (Dr. S. C. Bradford, Science Library, and Prof. A. F. C. Pollard, president of the Institut International de Bibliographie) has been formed to advise and assist in the adoption and use in Great Britain of the Universal Decimal Classification of the Institut International de Bibliographie, which has proved to be a suitable system for international use and is already widely employed. The international adoption of such a standard system of indexing would enable references to information on any subject, whatever their source, to be brought into their correct places in a bibliography, and this would tend to the preservation and freer exchange of knowledge in every intellectual field. Any one interested is invited to communicate with the Association of Special Libraries and Information Bureaux, 26 Bedford Square, London, W.C.1.

WE regret that by an error the official spelling of Kanchenjunga was incorrectly given in a note in NATURE of July 12 (p. 69). The spelling now adopted by the Survey of India is that given above.

THE summer issue of *The Fight against Disease*, the journal of the Research Defence Society, contains the annual report of the Committee, and an appeal is made for additional support as the expenditure has been £400 in excess of income during the last four years. The fourth Stephen Paget memorial lecture, by Mrs. Edward Mellanby, on "Diet and Dental Disease", is reported, and gives an interesting survey of the subject, illustrated with plates, as well as demonstrating how much we have learned on this subject from experiments on animals.

THE Cambridge Instrument Co., Ltd., has published a catalogue (No. 162) of alternating current instruments suitable for high frequencies. Recent progress in radio telegraphy and telephony has produced a demand for accurate instruments of this type. In reading the catalogue, we were specially interested in the alternating current potentiometer, the standard mutual inductometer, and the capacitance bridge, all designed by Albert Campbell. We also noticed the thermionic voltmeter designed by E. B. Moullin, which has both scientific and industrial uses. It has the unique qualities of absorbing practically no power from the circuit and possessing very little capacitance. At low voltages it is about forty times as sensitive as an electrostatic voltmeter. The Cambridge Instrument Co., Ltd., has also published a very useful Supplement to List No. 162, describing the best methods of measuring inductance, capacitance, and resistance with the instruments given in the list.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant for work on virus diseases of the potato—The Establishment Officer, Department of Agriculture for Scotland, Queen Street, Edinburgh (Sept. 27). A city engineer and surveyor to the Urban Sanitary Authority—Chairman of the Health Committee, under cover to the Town Clerk, Municipal Buildings, Liverpool (Sept. 30). A principal of the Aston Technical College—Chief Education Officer, Education Office, Margaret Street, Birmingham (Sept. 30). An assistant inspector of education and agricultural assistant—Director of Education, Springfield, Maidstone (Oct. 6). A principal of the Constantine Technical College, Middlesbrough—The Acting Secretary, Education Offices, Middlesbrough (Oct. 8). A junior assistant (male) in the directorate of ballistic research—Chief Superintendent, Research Department, Woolwich, S.E.18. An advisory agricultural chemist under the scheme of the Ministry of Agriculture and Fisheries for the provision of technical advice to farmers—The Registrar, University, Reading. A full-time teacher of engineering at the Chelmsford School of Science and Art—E. W. Alston, Education Office, 80 Duke Street, Chelmsford. A water and sanitary engineer for the Public Works Department, Trinidad—The Crown Agents for the Colonies (quoting M/2269), 4 Millbank, S.W.1.

Research Items.

Maori Fortification.—The *Records of the Auckland Institute and Museum*, vol. 1, No. 1, contains an account of the examination of the Piraunui Pa at Matawhana, Waikato, N.Z., by Messrs. J. W. Delph and Gilbert Archey, director of the Institute. The elaborate terraces of the Maori fortification are situated on natural strongholds formed by series of rock-capped headlands of the high rhyolite plateau of Central Waikato. The general layout of the fortifications is as follows: (1) A flat portion of the *marae* high up on a broad spur, below which is (2) a series of terraces on either side of the steeper ridge formed by the narrowing spur, leading down to (3) a still narrower and much steeper sided ridge cut across by a deep fosse and so forming a strongly protected approach to (4) the stronghold and citadel, a rhyolite-capped, vertical-walled spur rising with precipitous cliffs above the Waikato valley. The *pa* is very rich in storage pits of both the subterranean and semi-subterranean type. The former are built on flat ground wherever available, the latter at the base of some of the terrace walls. The subterranean pits are 6–9 ft. in diameter and about 5 ft. to the dome. In one which was cleared it was found that the floor was divided into bins, which would indicate its use for the storage of roots. In one, the original door-frames were still in place, tightly fitting to keep out the loose soil. Resting on the upper edge of one was a slab, the wood being well cut and originally about 2 in. in thickness. These pits penetrated into the hard rhyolite, and it was possible to see the method of working. Blocks of stone were worked behind or undercut so as to enable large slabs of rock to be broken off. The finish showed a skill which would not disgrace the efficient tools of a modern mason.

Marine Mollusca of Islands of the West Coast of Mexico.—In three consecutive papers, A. M. Strong and G. D. Hanna give the marine molluscan faunas of some islands off the west coast of Mexico visited on an expedition sent out by the California Academy of Sciences in 1925 ((*Proc. Calif. Acad. Sci.*, 4th Series, vol. 19). Each paper consists of a full list of all the known species with introductory illustrative remarks. Guadalupe Island, which lies about 180 miles south-south-west of San Diego, California, is represented in the Academy's collection by 87 species, of which 9 appear to be new. Almost all are shore or shallow water forms and some have a wide northern range. Their presence, the authors hold, can be most satisfactorily accounted for on the supposition that the fry or spawn were transported on masses of floating kelp by a current at some time running along the southern Californian coast and turning out to sea at an angle that carried it past the island. In the Revillagigedo Islands collections were made at Socorro and Clarion islands and 61 species are recorded, the bulk of which would seem more properly to belong with the faunas of the Galapagos Islands or Panama than with that of the Gulf of California. The Revillagigedo fauna has the character of a waif fauna arrived by chance. The islands have probably not been connected to the mainland, even by a shallow submarine ridge, during late geological time and do not seem to have existed at all for a sufficiently long period for the mollusca to have developed insular species. Tres Marias Islands, where the expedition made a short stay, have been comparatively frequently visited before, but the list of known forms of marine mollusca has now been brought up to 211 species.

Starfishes of the Pacific.—A monograph of the "Asteroidea of the North Pacific and Adjacent Waters", by Prof. W. K. Fisher of Stanford University, California, is published as *Bulletin* 76 of the United States National Museum. Part 1 was issued in 1911, Part 2 in 1928, and now the work is completed by a third part, in large quarto, of which 356 pages are numbered as such, while other intervening pages bear outline or half-tone illustrations on one or both sides and are numbered as 93 plates. These bear descriptions and figures of the subfamilies of Asteriidæ—Asteriinæ, Notasteriinæ, and Neomorphasterinæ—first of the northern hemisphere, then of the southern. There are 71 species recognised in the former and 76 in the latter. The former, however, receive much fuller treatment and occupy most of the volume. The Neomorphasterinæ appear to be confined to the southern hemisphere, while of the other two subfamilies, no southern genus is found without doubt in the northern hemisphere. Dr. Fisher establishes two new subgenera of *Leptasterias*—*Nesasterias* and *Hexasterias*, also *Bathyasterias*, a subgenus of *Diplasterias*, *Eremasterias* and *Neosmitaster*, new genera of Asteriinæ. The monograph contains useful keys and name-lists and the descriptions and diagnoses are drawn up with Dr. Fisher's customary care.

Philippine Land Shells.—An exceedingly useful and important "Summary of Philippine Land Shells" has been compiled by L. A. Faustino (*Philippine Jour. Sci.*, vol. 42) as supplement to Monograph 25 of the Philippine Bureau of Science in which his "Summary of the Marine and Fresh-water Mollusks" was given. The work in question consists of a list in systematic order of all species of land shells described or reported to occur in the Philippine Islands, with reference to the original description of each and the name of the individual island where it was found. There is also an alphabetical index to genera and synonymic notes, while occasion has been taken to append a small "Addenda to Monograph 25".

Earthquakes with Deep Foci.—The report of the Seismological Committee presented at the Bristol meeting of the British Association is the last drawn up mainly by the late Prof. H. H. Turner. One of its most interesting sections is that which relates to earthquakes with very deep foci. When the epicentres of these earthquakes are plotted on a map of the world, it is seen that they are not distributed at random but are confined to a comparatively small portion of the earth's surface. The boundary of this area, as drawn by Prof. Turner, is a roughly oval curve, reaching from the coasts of China and Japan to half-way across South America. The centre of the curve is on the equator in longitude about 150°. As the area covers the greater part of the Pacific, it is suggested that this distribution of deep-focal earthquakes offers some support to the theory that the moon was detached from the Pacific bed.

Dislocations of the Crust with the Japanese Earthquake of 1923.—Soon after this earthquake, the Military Land Survey re-levelled several routes in the central area. The results showed such remarkable changes that it was decided to measure the whole Kwanto district. The field-work was finished in 1927, re-observations of the primary triangulation-points having been carried out over an area of about 6500 square miles, and of the secondary and tertiary points over an area in the severely shaken region of about 3000 square miles. A summary of the results is given in English by R. Sakuryobu in the *Bulletin* of the Imperial Earthquake Investigation Committee (vol. 11, No. 4, pp. 1-80; 1930). The base-line lies

in one of the most devastated regions to the north of Sagami Bay. The new measurement made in 1924 showed that, since 1910, its length of about 3¼ miles had increased by 9·7 in. The greatest displacement of a primary point is that of 11 ft. 7 in. in the island of Oshima, but this is exceeded in five of the tertiary points, the maximum being 12 ft. 6 in. To the north of Sagami Bay and for about 14 miles inland, the ground was elevated, the greatest rise being 6 ft. 1 in. near Oiso. In the area of subsidence farther north, no point sank by more than 4 ft. 2 in. In the Boso peninsula, the change is usually one of elevation, the greatest rise being 6 ft. 3 in. at its southern end. Near the centre of the peninsula, however, there are a few small areas of depression, in one of which the ground has subsided by so much as 5 ft. 7 in.

Electrical Resistance of Ferro-magnetics.—The issue of the *Physikalische Zeitschrift* for June 15 contains an account of the measurements of the changes of electrical resistance of iron and nickel wires when magnetised longitudinally, by Dr. O. Stierstadt, of the Göttingen Institute of Applied Electricity. The wires were magnetised in a coil giving fields up to 250 gauss and their resistances were measured by means of a Kelvin double bridge. No influence of the direction or magnitude of the bridge current on the resistance of the wires in any field could be detected. The change of resistance on magnetisation was in all cases found to be an increase and the fractional increase was found for iron $10^{-20}B^4$ and for nickel $10^{-15}B^{3\cdot 4}$, where B is the magnetic induction in the material. The changes of resistance show a small hysteresis effect which probably accounts for the fact that some observers have found a decrease of electrical resistance in weak magnetic fields.

Alternating Stresses and Single Crystals of Metals.—Studies of the behaviour of single crystals of metals subjected to alternating stress have hitherto been confined mainly to crystals of the cubic system. From a theoretical point of view, it is important to know whether the planes of greatest atomic density or the lines of greatest density are the principal determining factors in mechanical slip. For this reason special interest attaches to two papers by H. J. Gough and H. L. Cox in Vol. A127 of the *Proceedings of the Royal Society*, dealing respectively with the behaviour of single crystals of zinc and antimony under alternating torsional stresses. Antimony was chosen because the planes of maximum atomic density in this metal do not contain any of the lines of maximum density, but the results were inconclusive, as the specimen could not be made to deform by slip, but cracked along certain crystal planes. The experiment is to be repeated with bismuth, which has a greater degree of plasticity. On the other hand, zinc, which has a close-packed hexagonal lattice, has given very satisfactory results. Slip occurs, as in static testing, on the basal plane, and its direction is that of the most highly stressed primitive direction. The twinning planes have been accurately determined, and it has been shown that the occurrence of twins as well as of slip-bands is controlled by the criterion of maximum resolved shear stress on the slip plane. Twinning in zinc has many features of interest, some of which are explained and others noticed for the first time in this paper, which is very fully illustrated.

Pulsations in Rotary Converters.—About thirty years ago, Gisbert Kapp and Bertram Hopkinson wrote papers on the abnormal working of synchronous motors. Explanations were given of their irregular working in certain cases and formulæ were obtained for the pulsations which, superposed on the steady running motion, produce the phenomenon of phase swinging. Hopkinson's theory, which shows how these pulsations can be damped by suitable devices, has proved of great use in practice. The analogous problem of the rotary converter can be treated in a similar way. This device consists of a machine which acts both as an alternating current synchronous motor and as a direct current dynamo. It takes alternating current in at one set of terminals and delivers direct current at the other, the power lost in the transformation being at the most a few per cent. These machines when running on a fluctuating load sometimes run irregularly owing to the pulsations produced. H. Cotton, in the *Journal of the Institution of Electrical Engineers* for August, discusses theoretically the theory of the motion in this case. The violent pulsations are caused when the free and the forced periods or harmonics of either synchronise. Formulæ are obtained for them and a rough verification is given by experimental results. The particular case when the machine is short circuited is considered. The mechanical analogy given for this case is the motion of a ballistic pendulum. Incidentally, considerable light is thrown on the requirements for the quick-acting circuit breakers which are in common use on the direct current side of these machines.

The Glass Electrode.—The use of the glass membrane electrode in determining hydrogen ion concentrations, although it has recently been shown by McInnes and others to be liable to error, is extending, and the description of a triode value arrangement for use with the electrode, given by G. B. Harrison in the July number of the *Journal of the Chemical Society*, is therefore of interest. The preparation of a new type of glass electrode is also described in the article. The technique is fully described and the arrangement permits of an accuracy of 0·02 pH unit over the range 1 to 12.

Molecular Weight of Legumin.—An investigation of the molecular weight of the protein legumin from vetch (*Vicia sativa*) by the ultracentrifuge method is described by Sjögren and Svedberg in the August number of the *Journal of the American Chemical Society*. The two proteins, legumin and legumelin, were separated by a process described in detail. A study of legumelin showed that it is not a simple protein. Legumin, on the other hand, is homogeneous with regard to molecular weight, the mean value of which was found to be 208,000 in a phosphate buffer of pH = 6·8. This, and other constants determined, agree within the limits of experimental error with the values for five other vegetable proteins previously investigated. The molecules of legumin are spherical, with a radius of 3·96 $\mu\mu$.

Density of Carbon Dioxide.—Especial interest attaches to the density of carbon dioxide on account of its close relation to several equations of state. In the June number of the *Canadian Journal of Research*, Cooper and Maass describe measurements of the density of the gas of sufficient accuracy to permit of direct extrapolation to zero pressure so as to give the limiting density of the gas. From this, the atomic weight of carbon, 12·0033 ± 0·002, follows directly. It was found that the graph representing the apparent molecular weight at 0° plotted against the pressure was a straight line. Full experimental results are given in the paper. The value of the molecular weight at S.T.P. agrees very well with that obtained by Guye from the weight of a normal litre.

Philippine Archæology.

PROF. H. OTLEY BEYER, head of the Anthropological Department of the University of the Philippines, has collected important archæological material during the last four years. In 1926 the construction of a dam on the Novaliches River brought to light a prehistoric village and cemetery which within the space of four months yielded some eighteen thousand specimens. During the next three years extended reconnaissance and excavation in the neighbourhood, mostly within the province of Rizal, brought to light nearly a hundred sites and an enormous amount of material, running into scores of thousands of objects.

Previously to these discoveries, the archæology of the Philippines earlier than, say, a thousand years ago was a blank. Almost at a stroke it has been carried back at least to the early neolithic and possibly earlier. Although the material has still to be worked out in detail, certain broad conclusions are possible. These are summarised and their bearing upon the prehistory of Eastern Asia indicated by Prof. Roland B. Dixon in vol. 69, No. 4, of the *Proceedings* of the American Philosophical Society.

On the Novaliches site five archæological horizons were distinguished. Of these, the most recent contained celadons, porcelains, and other ceramics, some dating back to the early Sung dynasty. This was preceded by two strata belonging to the iron age, below which were two stone age levels, one characterised by polished implements associated with fairly good hand-made pottery, and the earlier by implements only partly polished, associated with a cruder type of pottery. The extended observations in the province of Rizal revealed two earlier stone age phases, of which one is marked by deeply patinated chipped implements identical with the so-called 'Bacsonian' of Tonkin and not accompanied by pottery, to which both stratification and typology justify the application of the term mesolithic; and a second in which typical microliths and deeply patinated Mousterian-like forms suggest, in Prof. Dixon's view, the conclusion that they are palæolithic, even though the evidence of stratification is lacking.

While it would be well to accept Prof. Dixon's final suggestion only with very considerable reserve pending further evidence, there can be no two opinions as to the great value of Prof. Beyer's contribution to Philippine archæology. Its full significance, however, will not become apparent until it has been correlated and studied comparatively with the archæological material which has been, and is still being, brought to light in China, Tonkin, the Malay Peninsula, and the Dutch East Indies. When the time is ripe for the collation of the material from the whole area, and further, when it is brought into relation with the material from India, it should throw a flood of light on the racial and cultural drifts of eastern Asia.

In commenting on the material from the iron age strata in the Philippines, Prof. Dixon points out the similarity, and in some cases identity, of the iron and glass objects to those found in the dolmen tombs and urn burials of southern India, and refers to similar finds in the Malay Peninsula, Java, and Borneo. As he goes on to urge the necessity for research in southern India as a 'way-station' between western Asia and the Philippines, it may not be inopportune to refer to the work of the Indian Research Committee of the Royal Anthropological Institute on the archæology of the bead in India. A collection of type series of Indian beads has been formed which is available for students, and the first instalment of the Committee's work, with coloured illustrations of beads from southern India and Sarawak, is, we understand, to be published as a special number of *Man* in October.

Seventy-fifth Annual Exhibition of the Royal Photographic Society.

THE annual exhibition of the Royal Photographic Society was opened at 35 Russell Square, London, W.C.1, on Saturday, Sept. 13, and will remain open until Saturday, Oct. 11, from 10 A.M. to 9 P.M. each weekday except Tuesdays and Fridays, when it will be closed at 6 P.M. The following lectures are being delivered during the exhibition, at 7 P.M. on the evenings stated: Tuesday, Sept. 16—"The Mystery Bird of Britain and other Stories from Birdland", by Oliver G. Pike; Tuesday, Sept. 23, "From Alp to Apennine", by J. Dudley Johnstone, president of the Royal Photographic Society; Friday, Sept. 26, the lantern slides selected for the exhibition will be projected on the screen; Tuesday, Sept. 30, a popular lecture on astronomical photography, by F. J. Sellers; Friday, Oct. 3, "Kew Gardens—Some of its Beauties in Colour", by F. R. Newens; Tuesday, Oct. 7, "Tunis to Algiers", by the Rev. H. O. Fenton; Friday, Oct. 10, the amateur cinematograph films on 16 mm. (sub-standard) film which have been selected for the exhibition will be projected on the screen.

This exhibition may be divided roughly into three classes: pictorial work, record work, and research concerning photographic materials.

The pictorial work shown is from all parts of the world and is, of course, first-rate. Practically all of the important methods of photographic technique in both colour and monochrome are represented.

Photographic recording is now used as an aid to a vast number of activities; teaching, advertising, and research all make use of it. The exhibition contains examples of all these applications. In the natural history section are many beautiful photographs of wild animals and birds in their natural surroundings, and also of other objects. Two striking prints by Mr. J. A. Speed show a field-mouse in the act of rescuing its young. Mr. D. P. Wilson exhibits a good series of marine subjects, including one of Golden Star corals found on the shore at very low water in Cawsand Bay, Cornwall. Mr. W. C. Davies has three prints of the fossil remains of some very large insects, one being a kind of dragonfly with a wing span of about 12 inches.

Archæologists will be interested in several series of photographs of the Roman Wall and other Roman remains shown by C. Mason and G. E. Peachey. Aerofilms Ltd. show a vertical view of Ashdown Forest on which may be noted the faint indication of a Roman road and an enclosure probably built sometime about the commencement of the Christian era. This print shows the way in which aerial observation assists in the search for ancient remains which are almost invisible at ground level.

As usual, cloud photography is very well represented, and for his work in this field Mr. G. A. Clarke has been awarded a medal.

Last year note was taken in NATURE of some very fine spark photographs by P. B. Quayle, who showed several records of bullets and shot clusters in flight.

In this present exhibition, Mr. Quayle shows the bullet just as it penetrates a steel plate and just after, its jacket stripped off and its lead core broken into fragments mingling with flying particles of the steel plate itself. The main part of his exhibit is, however, devoted to a study of guns at the instant of firing. It is shown that the 'high shooting' of revolvers is not nearly accounted for by change of aim due to recoil, but is due in part to an upward velocity given to the bullet as it leaves the muzzle. Another series of photographs shows the bursting of shot guns caused by plugs of clay inserted in the muzzle before firing, a fine object-lesson to the sportsman who is inclined to carry his gun carelessly over clayey country.

General Motors Research Laboratories show a photographic study of combustion in engines. The examples given are for various mixtures of fuels. Some of these show pressure diagrams obtained during detonation.

The very great extension of research in the photographic industry during recent years is well shown in this exhibition. Five pieces of apparatus are shown, each one being of considerable importance. Kodak Ltd. exhibit a sensitometer designed for testing sensitive materials; a colorimeter intended for checking the colour of materials, such as sensitive papers, wrapping papers, cards, etc.; a goniophotometer for studying the polar reflection curves for cinematograph screens and also a mirror arc for use with the Kodascope apparatus for projecting 16 mm. cinematograph films. The British Photographic Research Association shows the latest design of photoelectric density meter as now marketed.

Dr. F. C. Toy and G. B. Harrison have recently succeeded in making a very thorough study of the photo-conductance of silver bromide. By means of models they now show some of the principal facts arising out of their work. Included in the same exhibit are specimens of large single crystals of silver bromide. These were prepared by methods similar to those employed for making single crystals of copper. The samples shown are probably the largest single crystals of silver bromide which have yet been made.

Ilford Ltd. show some examples of the influence of dyes on the spectral sensitivity of photographic materials, together with a very fine example of a clear photograph taken on a misty morning by the use of a plate sensitised to the infra-red and with a so-called 'infra-red filter'.

An instructional exhibit of great interest is shown by the research laboratories of Messrs. Thomas Illingworth, Ltd. It illustrates how the development of the negative must be controlled in order to yield a good print on a given printing paper. For comparison, the original object is shown in its proper lighting by the side of various negatives and prints. The limitations of photographic prints on paper are emphasised by including with the prints a positive transparency. The latter is seen at once to be a much more faithful representation of the original. This was so striking to the writer that he at once went on to see again the pictorial lantern slides in the exhibition. These are arranged for viewing as transparencies, and when so displayed give a demonstration of photographic rendering of tone which is considered by many people to be far more beautiful than that obtained by any other method. It is unfortunate that much of the beauty is lost when the pictures are projected on to a screen.

S. O. R.

Recent Studies of the Foraminifera.

THE Foraminifera constitute a class of Protozoa which provides many problems of great interest for the morphologist, the systematist, and the palæontologist. Their remarkable life history, the beauty and elaboration of their shells, and the records of their occurrence in the rocks from the most ancient times have been the subjects of many elaborate and important treatises in recent times. It is difficult for anyone to follow the progress of our knowledge of the group in all these directions; but as in other groups of animals, it is the work of the systematists which is most usually set aside as suitable only for the perusal of the specialists.

Accurate description and illustration of the various forms of animal life whether species or varieties is the essential basis upon which the construction of reasonable morphological theories must rest, and it is not unreasonable, therefore, to direct attention to the excellent work that is being done in the Foraminifera by Heron-Allen and Earland [1] in Great Britain, and by Hofker [2] in Holland.

The time is past when a study of the external form of the shells was considered sufficient. Nowadays the use of sections for the observation of the canal system in their walls, in the case of the arenaceous forms, the use of skiagraphs, when possible, and the careful search for dimorphism or trimorphism are necessary for the accurate determination of genera and species.

The number of specific names that have been given to members of the Foraminifera is so enormous that there may be some misgiving as to the validity of many of the species. No doubt many of the old names will disappear, but it is always difficult to determine the degree of discontinuity between a new form and an old one which justifies the constitution of a new species, and particularly so in the lower orders of animals where variation is wide and breeding experiments at present impracticable.

The recent investigations of Heron-Allen and Earland, in which the most elaborate methods were used, lend support to the view that among the free unattached Foraminifera there may be a true specific discontinuity.

Globigerina cristata, for example, from the deep sea mud of the South Atlantic seems to be, undoubtedly, a good species. From the smallest immature forms 0·08 mm. in diameter through a long series to the largest mature forms, 0·18 mm., the characteristic features which distinguish it from the other species of the genus can be observed. The same may be said of *Ehrenbergina crassa* and several other species described and figured in these papers.

Among the forms which become attached to foreign objects at the bottom and lead a sedentary life the beautiful symmetries of the shell are lost and variations in growth and many other characters are rampant.

In the widespread and very common *Foraminifer Polytrema*, for example, with its endless varieties of ramification, there seems to be no specific discontinuity, and the same is probably true of the genus *Gypsina*.

This has led to a great deal of confusion in the systematics of the group and to the proposal for the suppression not only of species but even of genera, which is quite startling to some of those who have taken an interest in these forms. Thus Hofker in a recent very fine monograph has declared that *Ramulina herdmani* is identical with *Carpenteria utricularis*

and "Sporadotrema is nothing else than a typical Carpenteria".

Without fully accepting all Hofker's conclusions, it may be said that his work has brought additional and important evidence of the extraordinary variability of these sedentary Foraminifera as compared with that of their allies which remain free throughout life.

This does not necessarily lead to the conclusion that specific discontinuity does not occur in any of the sedentary Foraminifera. That would be an extreme view which is not warranted by the facts. Such species as *Sorosphaera depressa* and *Schizammina labyrinthica* described by Heron-Allen and Earland in these papers seem to be good species. But it does suggest that in some cases such discontinuity has been lost or, perhaps, has not yet been gained, and that their survival depends not on the evolution of specific characters but on their extreme adaptability to the environment by their great variability.

Space does not permit comment on many other interesting features of these papers, but attention may be directed to the account given of the remarkable family the Pegidiidæ which have an extraordinarily thick shell and an unusual system of apertures. In this paper there is a reproduction of Dr. Orbigny's original sketch for a drawing of *Rotalia dubia*, a long-lost species now included in the Pegidiidæ.

Angiosperm Origins.

G. R. WIELAND has a very interesting discussion of the origin of Angiosperms in the *Proceedings* of the International Congress of Plant Sciences held at Ithaca, vol. 1, pp. 429-456 (George Banta Publishing Company, Menasha, Wisconsin, 1929). Naturally this account contains a particularly interesting recapitulation of the main features of the discoveries in the Cycadeoideæ with which the author's name is now linked through the genus *Wielandiella*, established as the result of Nathorst's fine reconstruction of difficult Swedish and Yorkshire material; but this general account is particularly valuable as it synthesises the available material, in a problem which ranges the whole globe and a considerable part of geological time.

Wieland argues that the Jurassic was a time of leaf and carpellary change in the earlier Angiosperms, just as the Cretaceous was the time of continued stem and floral change in fully characterised Angiosperms. He points out that the abundance of Angiosperms in Cretaceous rocks is due not merely to the increasing complexity in the phylum, but also to the greater thickness of the more and more recent plant beds. From this point of view he advises the botanist not to take too seriously the geologists' suggestion that the Angiosperms originated locally and suddenly; rather this impression may be due to imperfections in the earlier plant record; thus he calculates that of Jurassic times our plant records represent perhaps a tenth of one per cent of the species then existent, and those recorded mainly by dissociated leaves, stems, etc., more rarely by flowers and fruits. Some impressions of interesting new, possibly Dicotyledonous, fruits are recorded from Rhætic plant beds of the Argentine. Wieland states that the fossil series of insects described from these beds "mark the Argentine Rhætic as one of the most important fossil localities in the world".

Wieland concludes that there is every reason to regard the Angiosperms, "so far as actual descent goes, as old, quite as old as pines, and polyphyletic". He points out also that, from studies of fossil forms, it is easy to get a false impression that giant forms predominated in fossil periods, where specialised types make up the bulk of the fossil series. But this conclusion is not justified; the Cordaites varied from types with leaves ten feet long to those with narrow grass-like blades. Wieland suggests that "the contrast between the flowers of *Drimys*, in some species about the size of those of the chickweed, and related flowers a foot across, has surely been paralleled many times in the geologic past", so that many small fleshy forms of megasporophylls were probably grouped into seed cones allied to *Wielandiella* in Rhætic times.

Fluctuations in Fisheries.

ON April 12, 1929, the Conseil Permanent International pour l'Exploration de la Mer held in London a special meeting to discuss the present state of our knowledge concerning fluctuations in the abundance of the various year-classes of food fishes. So much interest is now being taken in this important branch of fishery research that no less than nineteen papers were read at the meeting, a full report of which has recently been published.*

When the Council entered upon its international collaboration thirty years ago, an enormous amount of work had to be done in the systematic determination of the various species, in ascertaining their geographical occurrence and distribution, and in locating their spawning grounds. As this work advanced, and more refined methods of biological analysis were brought to bear upon the steadily accumulating masses of data, it gradually became clear that to think only in terms of species was inadequate, and new concepts of definite tribes or races of the various species had to be evolved in order more clearly to grasp the true state of affairs in Nature. Still further research revealed, moreover, that these newly discovered tribes themselves often occur in several more or less distinct groups, depending upon such factors as age, size, and sexual maturity.

These comparatively recent racial investigations, and especially the study of the varying age-distributions in the stock of our chief species of food fishes, have opened up new vistas of marine investigation. They have explained in many cases the amazing fluctuations in the yield obtained by the fishing industry from year to year, and, more important still, it has even been possible to forecast future fluctuations—an achievement of very considerable practical value.

A paper read by Dr. Harold Thomson outlining his work on the haddock may be taken as typical of this branch of marine research, and indicates the possibilities inherent in the results so far obtained. After discussing the incidence and amplitude of brood survival, Dr. Thomson proceeds to consider the

* Fluctuations in the Abundance of the Various Year-Classes of Food Fishes. Conseil Permanent International pour l'Exploration de la Mer. Rapports et Procès Verbaux des Réunions, vol. 65, pp. 188. (Copenhague: Andr. Fred. Høst et Fils, 1930.) 7.25 kr.

possible causes underlying them. The following are suggested:

(a) Variation in the locality of the spawning ground. In the case of the haddock, the main centre of spawning activity may vary in position by so much as almost 2° of latitude. The effect of this movement of location is probably mainly an indirect one in that it influences the primary distribution of the eggs and fry.

(b) The numbers and average age of the spawning fish. The spawning shoals are always composed chiefly of haddock from three to six years old, and therefore include a series of broods differing in themselves in initial numerical strength. As there is an appreciable difference between the spawning locations assumed by younger and older haddock, the outcome may well be that the eggs and fry resulting from the spawning of younger fish predominating in one year will drift in quite a different set of currents from those resulting from the spawning of older fish predominating in another year.

(c) Early food supply. There is reason to suppose that the food requirements of the earlier (fry) stages are highly specialised, and that the necessary food organisms fall short of the demand to a greater or less extent in certain years. This, possibly, is the main cause underlying the not unusual wholesale failure of a brood.

Finally, as a result of careful analysis of the existing composition of the North Sea haddock, Dr. Thomson has been able to formulate the following tentative estimate of the immediate (1929) outlook for the fishery. "As the 1927 brood has proved to be almost a failure, catches may be expected to dwindle below the normal from the late autumn until well into next year (1930). About August of 1930 there should be a marked increase in the catches owing to the upgrowth of the very successful 1928 brood. In 1931 still greater catches should accrue. This is as far as can be seen ahead, for by the autumn of that year the influence of the 1928 brood will be waning and the next determining factor will be the quality, as yet unknown, of the brood of 1929. Estimations are therefore necessarily restricted to about two years ahead in the case of the southern portion of the North Sea. If these general anticipations prove correct an attempt should certainly be made to form seasonal or even monthly forecasts for the main fishing grounds."

Dr. Johan Hjort, in a brief survey of the methods and general principles underlying investigations into fluctuations in the stock of fishes, lays great stress upon the importance of the work. He suggests the setting up of an international biological organisation for the regular observation of age-distribution in the stock of our food fishes and of the relative—in time perhaps even the absolute—numerical strengths of the year-classes. Such a biological service, dealing conjointly with both biological statistics and a biochemical study of the fluctuating conditions in the sea, would in due course throw new light on many problems, and render possible a trustworthy fishery prediction service.

Linnæus and the Production of Artificial Pearls.

LINNÆUS was a great naturalist, but one gathers a fresh idea of his manifold interests in Nature from the series of articles in *Svenska Linné-Sällskapets Årsskrift*, Årg. 13, 1930. One of the most curious of these papers, by Gustaf Drake, recounts an incursion of Linnæus into the artificial pearl trade. In the course of his journey through Lapland, Linnæus paid a visit to a pearl-fishery, where the pearls were derived from fresh-water mussels. Knowing that various species of mollusca, both fresh-water and marine, could produce pearls, he formed the opinion that theoretically they could be formed by any shell, and turned his attention to their artificial production. He carried out several successful experiments, and Beckmann records that in 1765 he was shown by Linnæus himself four or five real pearls lying within the shells of *Mya margaritifera*, with the proud announcement: "*hos uniones ipse artificio meo arcano confeci.*" Before this time, however, word had got abroad of Linnæus's pearl-making secret, and in 1761–62 he was induced to demonstrate his method to Parliament. As a reward he was allowed the right of nominating his own successor, and chose his only son. But he also had a tempting offer from a private person for the monopoly of his pearl-producing method, though he did not accept it.

It is interesting to recall that the manuscripts explaining the pearl-producing method of Linnæus came into the hands of Sir James Smith and to repeat the latter's strong opinion regarding the exploitation of such scientific researches, conveyed in a letter dated Nov. 28, 1821: "The only *pearls* I ever expected from the possession of your illustrious countryman's literary treasures are *pearls of science*, in which I have not been disappointed. I am contented with these, and am happy that Sweden appears satisfied with what I have done for the honour of Linnæus and for the science to which I have devoted myself, in humble imitation of that great man. I believe I am possessed of manuscripts of his own explaining the secret of producing pearls. I have also in his own cabinet of shells specimens of pearls so produced, and of mussel shells in various states upon which experiments have been made. I have no intention of carrying out the scheme—still less of paying £500 for any further information, nor, in short, of entering at all on the subject, for which I have no leisure." Can any of our readers say whether the experimental shells referred to are still in existence, and if so, whether the public has ever had an opportunity of seeing so interesting an exhibit ?

The natural philosophy of Linnæus is the subject of another very interesting contribution in the same *Årsskrift*. The Rev. Dr. Elis Malmeström considers that although Linnæus scarcely formulated a natural philosophy of his own, his ideas moved in the direction of such a philosophy, and in the preface and introductions to his various works he often indicated the direction of his thoughts about the universe, creation, life and its purpose. Three transitional stages of development are observable. In the first, ending about 1735, Linnæus expressed in the first edition of "Systema Naturae" a static idea of Nature which he had gathered from the Bible and especially from the creation myths of the Old Testament. Such an idea is presupposed by the whole of his systematic work, and he never really forsook it. The second period, up to about 1750, saw an endeavour to unify the discrepancies which appeared to be increasing between creed and science. The fixity of species seemed less assured than formerly, but Linnæus stood firm against materialism, and adopted the physico-theology of his day. The third period, from 1750 until his death, marked a strong drift toward theodicy and a teleological view of Nature. He now adopted a natural theology, in which everything worked for the glory of God. Behind his thoughts on natural philosophy lay a religious craving for harmony.

Historic Natural Events.

Sept. 21, 1486. Sweating Sickness in England.—According to Holinshed, "in this year a new kind of sickness invaded suddenly the people of this land passing through the same from the one end to the other. It began about the one and twentieth of September and continued until the latter end of October being so sharp and deadly that the like was never heard of to any man's remembrance before that time. For suddenly a deadly burning sweat so assailed their bodies and distempered their blood with a most ardent heat, that scarce one amongst a hundred that sickened did escape with life."

Sept. 21, 1741. Shower of Gossamer at Selborne.—Gilbert White records ("Natural History of Selborne") that before daybreak "I found the stubbles and clover grounds matted all over with a thick coat of cobweb. . . . When the dogs attempted to hunt, their eyes were so blinded and hoodwinked that they could not proceed, but were obliged to lie down and scrape the encumbrance from their faces with their forefeet. . . . About nine, an appearance very unusual began to demand our attention—a shower of cobwebs falling from very elevated regions, and continuing, without any interruption, till the close of the day. These webs were not single filmy threads, floating in the air in all directions, but perfect flakes, or rags: some near an inch broad, and five or six long, which fell with a degree of velocity, that they were considerably heavier than the atmosphere. On every side, as the observer turned his eyes, he might behold a continual succession of fresh flakes falling into his sight, and twinkling like stars, as they turned their sides towards the sun. How far this wonderful shower extended, it would be difficult to say; but we know that it reached Bradley, Selborne and Alresford, three places which lie in a sort of triangle the shortest of whose sides is about eight miles in extent." The gossamer descended even on the highest part of the downs.

Sept. 23, 1834. The "Padre Ruiz" Hurricane.—This was the most severe hurricane on record in Santo Domingo; it takes its name from the fact that it began during the funeral service over a priest of that name. The loss of life and property was appalling; everything was laid waste, large areas of timber being torn up by the roots. Hundreds of houses were destroyed and many vessels were lost. The stone church of San Antonio was demolished, and its ruins have been left as a monument of the storm. The downpour of rain was so great that a fisherman was drowned in the principal market, as no one dared to go into the street to assist him.

Sept. 23, 1924. Inundation at Leningrad.—At 10 A.M. the waters of the Neva commenced to rise rapidly and by 7.15 P.M. stood 12 feet above their ordinary level. This flood was second only to that of November 1824 and caused enormous damage. The flood was caused by a deep depression over Finland, resulting in westerly winds over the Gulf of Finland, which heaped up the waters and impeded the flow of the Neva. The actual flood was due to sea water.

Sept. 25, 1909. Magnetic Storm.—A magnetic storm, of brief duration but of unusual severity, began abruptly at noon on Sept. 25 and ceased about 15 hours later. The ranges at Greenwich—193′ in declination and 1710γ in horizontal force—have not been equalled there for at least fifty years. An oscillation in declination of 3° within 15 minutes of time was recorded at Kew; at Stonyhurst an oscillation of $2\frac{1}{4}$° within 2 min., and one of 5° within 14 min. at Cheltenham, Maryland. An aurora accompanied the disturbance of the magnets; at South Kensington, in spite of cloudy or overcast skies, the green auroral line was easily seen with a spectroscope. A large sunspot crossed the central meridian on Sept. 23·8, and this was observed spectroscopically to be very active; about twenty-six hours before the commencement of the magnetic storm, the spot was for a time nearly obliterated by an overhanging cloud of brilliant calcium that probably represented a large active prominence.

Sept. 25, 1928. Waterspout off Deal.—An immense waterspout was reported over the sea about $4\frac{1}{2}$ miles off Deal. It was described as having a conical shaped top which was encircled by a large rainbow, with a remarkable background formed by heavy rolling clouds in which the sun was setting. It lasted for about ten minutes.

Sept. 26, 1902. Heavy Rain in Sicily.—On Sept. 25–27 a barometric depression travelled northwards from Tunis and settled over Sicily. It was accompanied by an extraordinary series of thunderstorms, in the course of which more than half the normal year's rainfall fell in five days. The most violent occurred at 7.25 A.M. on Sept. 26; it lasted only about half an hour but in that time several inches of rain fell. The total for the 24 hours at Linguaglossa was 16·7 in., and in five days (Sept. 25–29) 29·1 in. At San Alfio 23·3 in. fell in two days and 30·6 in. in five days. The storm of Sept. 26 was followed by extensive floods. At Modica, where three small streams meet, the flood was the first since 1833 and the worst on record; the water rose 10 to 20 feet above the level of the streets, and 111 persons lost their lives, while enormous damage was done. A rock weighing 90 tons was carried two-thirds of a mile by the force of the water.

Sept. 27, 1911. Tornado in Victoria.—A violent tornado, in the shape of a long inverted cone of cloud, appeared between Leichardt and Derby about 2.30 P.M. and travelled south-eastward, completing a course of 12 miles in about half an hour. Much damage was done by the wind to buildings, cattle, and agricultural machinery, and several persons were injured. The tornado was accompanied by heavy rain and hail, some of the hailstones weighing a pound.

Sept. 27, 1912. Heavy Rain.—At Wynaad in southern India an extraordinary rainstorm broke at 1.45 P.M., unaccompanied by wind but with a good deal of thunder and lightning. The storm lasted an hour, during which time the fall amounted to 9·75 in. The extensive lowlands were flooded to a depth of more than a foot.

Sept. 27-28, 1908. Floods at Hyderabad.—At Hyderabad in the Deccan, India, during the passage of a cyclone, more than 15 in. of rain, nearly half the annual total, fell in 36 hours, causing the river Musi to rise 60 feet. A considerable part of the city was ruined, more than 5000 persons lost their lives, and 100,000 were rendered homeless.

Correction. Sept. 10, 1903. Gale over British Isles. Line 5, *for* 5 mb. (1·4 in.) *read* 5 mb. (0·14 in.).

The nature of the reaction between acetylene and a mixture of bromine and iodine depends on the solvents used for the halogens (water, hydrochloric acid, chloroform). In the separation and determination of the amounts of bromiodoethylene, diiodoethylene, tetrabromethane, chlorobromoethylene, dibromethylene and chloroiodoethylene present, in view of the instability of these compounds on distillation, use was made of the properties of the azeotropic mixtures obtained by distilling with butyl alcohol.—**Marcel Winants**: Application of the method of successive approximations to the integration of certain linear trinomial partial differential equations of any order.

WASHINGTON, D.C.

National Academy of Sciences (Vol. 16, No. 6, June 15).—**E. M. East**: The origin of the plants of maternal type which occur in connexion with interspecific hybridisations.—**Dietrich C. Smith**: Melanophore pulsations in the isolated scales of *Fundulus heteroclitus*. The hydrogen ion concentration seems to be the most important single factor concerned.—**John H. Welsh**: Diurnal rhythm of the distal pigment cells in the eyes of certain crustaceans. Diurnal rhythm parallels changes of activity of animal. It continues even under constant illumination, but proximal pigment does not show same movement. Effects of chloretone and ligation of eye-stalk suggest that movements are controlled directly by blood and indirectly by nervous system.—**G. H. Parker**: The colour changes of the tree toad in relation to nervous and humoral control. The American tree toad is unable to adapt its mottling to the size of pattern on which it finds itself. The pattern becomes sharper or fainter but without modification of detail. Adrenalin makes the pattern light in colour and pituitrin makes it dark. Humoral rather than nervous control is suggested.—**Donald Statler Villars**: Equilibrium constants of reactions involving hydroxyl: a correction.—**G. A. Miller**: Groups of isomorphisms of an Abelian group.—**Arthur B. Brown**: (1) Coalescence of parts of a complex.—(2) An extension of the Alexander duality theorem.—**Richard C. Tolman**: More complete discussion of the time-dependence of the non-static line element for the universe. A theoretical development of the theory described in earlier papers.—**R. A. Millikan and I. S. Bowen**: The significance of recent cosmic-ray experiments. The experiments

discussed are (1) absorption coefficients on high mountains and at great depths in mountain lakes (Millikan and Cameron), (2) absorption of gamma rays in mountain lakes (Millikan and Bowen), (3) gamma ray absorption in the laboratory (Chao), and (4) coincidences in ionisation counters (Bothe and Kolhörster, and Curtis). The results are considered to favour the atom-building hypothesis of the origin of cosmic rays, which seem to be photons rather than electrons. On striking matter, these photons share their energy with an electron, producing beta rays of penetrating power of the same order of magnitude as the cosmic rays themselves.—**C. Hewitt Dix**: Motion on a lattice. A theoretical discussion.—**C. Y. Chao**: The absorption coefficient of hard γ-rays. Thorium-C″ is used as a source of γ-rays (λ4·7 X.U.) and a parallel beam is used. Measurements were made with a Millikan cosmic ray electroscope and also with an ionisation chamber connected with a vacuum electrometer. The ratio of absorption coefficient to number of external electrons per c.c. increased with atomic number of absorbing substance. This may be due to (*a*) scattering by electrons within the nucleus; (*b*) the fact that scattering of a tightly bound electron of atoms of high atomic numbers may be greater than that of a loosely bound electron; (*c*) true absorption due to the photoelectric effect.—**B. F. Skinner**: On the conditions of elicitation of certain eating reflexes. Rats were fed in a sound-proof box in a sound-proof room and the rate of feeding measured; the pieces of food are of uniform size and removal of each piece is recorded electrically. The graph of amount eaten against time is of the form $N = Kt^n$ where N = food eaten at time t and K and n are constants; K varies from animal to animal and day by day, but n is always approximately constant.—**Francis G. Benedict and Cornelia Golay Benedict**: The energy requirements of intense mental effort. Respiratory exchange was measured by a helmet which permits free vision and is without mouthpiece or nose-clip. The subject lies down after a 12-hour fast and remains quiet with as little mental activity as possible. Then he is asked to respond to ocular or auditory stimuli to determine the metabolic changes required by attention or alertness, and finally he is given three or four 15-minute periods of intense mental effort (mental multiplication). There is a noticeable increase in heart rate, increased volume of air passing through lungs, and slight increase in oxygen consumption. The effects are not cumulative, and increase in heat production, even with intense mental effort of this type, is only of the order of 3 or 4 per cent.—**William Hovgaard**: Bending of curved tubes. Formulæ for displacements and stresses previously obtained were tested on pipes from 4½ in. to 12 in. in diameter. Good agreement was obtained while the bends were well within the elastic limit. Plastic flow occurs along well-defined longitudinal zones.

Diary of Societies.

MONDAY, SEPTEMBER 22.

CERAMIC SOCIETY (Refractory Materials Section) (at the Building Trades Exhibition, Olympia), at 2.30.—W. J. Rees and J. H. Chesters: The Application of Tensile Tests to the Study of the Bonding of Refractory Materials.—C. R. F. Thelfall: Grog.—H. T. S. Swallow: The Influence of Atmosphere on the Load-bearing Capacities of Firebricks.

CERAMIC SOCIETY (Building Materials Section) (at the Building Trades Exhibition, Olympia), at 2.30.—F. L. Brady and E. H. Coleman: Influence of Firing Conditions on the Soluble Salt Content of Burnt Brick.—J. Williamson: Continuous Kilns for Burning Clay.—W. Emery: Red Roofing Tile Kiln Report.

TUESDAY, SEPTEMBER 23.

CERAMIC SOCIETY (Refractory Materials Section) (at the Building Trades Exhibition, Olympia), at 10.30.—W. Hugill: The Structure of Diatomaceous Earths in Relation to their Uses.—R. J. Sarjant: Works Tests on Refractories and Service Conditions.—W. Hugill and W. J. Rees: Effect of Repeated Burning on the Structure and Properties of Lime-bonded Silica Bricks. Parts II. and III.

CERAMIC SOCIETY (Building Materials Section) (at the Building Trades Exhibition, Olympia), at 10.30.—Ambrose W. Cross: British Bricks for British Roads.—G. A. Hodson: The Manufacture of Bricks for Road Paving in U.S.A. and Holland.—J. Bentley, jun.: A Few Observations on the Causes of a Particular Type of Crack encountered in the Manufacture of Plastic Machine-made Roofing Tiles.—W. Emery: Blue Brick Kiln Report.

INSTITUTE OF MARINE ENGINEERS, at 6.—Lieut.-Comdr. Sir August B. T. Cayzer: Presidential Address.

WEDNESDAY, SEPTEMBER 24.

CERAMIC SOCIETY (Refractory Materials Section) (at the Building Trades Exhibition, Olympia), at 10.30 A.M.—Council and General Business Meeting of Refractory Materials Section.

CERAMIC SOCIETY (Building Materials Section) (at the Building Trades Exhibition, Olympia), at 11.30.—Council and General Business Meeting of Building Section. The following papers will be communicated by title:—W. J. Rees and W. Hugill: The Effect of Iron Oxide and a Reducing Agent on the Rate of Inversion of Quartz.—W. J. Rees: Note on the Effect of Iron Oxide in Quartz Inversion.—J. W. Mellor: A Study of Pan Grinding.

THURSDAY, SEPTEMBER 25.

INSTITUTION OF LOCOMOTIVE ENGINEERS, at 6.—H. Kelway Bamber: Presidential Address.

SATURDAY, SEPTEMBER 27.

SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES (Autumn Meeting).—Visits to St. Paul's Cathedral and the Natural History Museum.

THURSDAY, OCTOBER 2.

SOCIETY OF CHEMICAL INDUSTRY (Bristol Section) (in the Chemical Department, The University, Bristol), at 7.30.—Prof. J. W. Hinchley: Air and Water.

FRIDAY, OCTOBER 3.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—S. J. Crispin: The Development of the Bridge.

SATURDAY, OCTOBER 4.

ROYAL SANITARY INSTITUTE (in the Assembly Room, Town Hall, Hereford), at 10 A.M.—Councillor Mrs. Luard: The Place of Women in Local Government.—G. H. Jack: The Preservation of the Countryside.—Councillor J. R. Barker: The Health Authority and the Milk Supply.

CONGRESS.

SEPTEMBER 29 TO OCTOBER 1.

FARADAY SOCIETY (in Laboratory of Physical Chemistry, Cambridge).—Discussion on Colloid Science applied to Biology.

Monday, Sept. 29, 2 to 4 and 4.30 to 7.—Equilibrium in Protein Systems. In Chair—Sir William Hardy, who will introduce the Discussion.

Prof. A. V. Hill: Membrane-Phenomena in Living Matter—Equilibrium or Steady State.

Dr. R. A. Gortner: The State of Water in Colloidal and Living Systems.

Prof. E. J. Bigwood: Distribution of Diffusible Ions in Gels.

Prof. W. Pauli: The Behaviour of Proteins towards other Colloids and towards Electrolytes.

Prof. F. F. Nord: The Biological Significance of the Physical Influence of Gases on Colloids.

Tuesday, Sept. 30, 10 A.M. to 11.15 A.M., 11.30 A.M. to 1 P.M., 2.30 to 4, and 4.30 to 7; and

Wednesday, Oct. 1, 10 A.M. to 1 P.M.—In Chair—Sir F. Gowland Hopkins, who will introduce the Discussion.

Dr. Honor B. Fell and Dr. Wilmer, followed by Kinematograph Studies of Living Cells by Dr. Canti: The Structure, Behaviour and Physiological Characteristics of Vertebrate Cells cultivated *in vitro*.

Prof. E. Faure-Fremiet: The Kinetics of Living Matter.

Prof. R. A. Peters: Surface Structure in the Integration of Cell Activity.

Prof. O. Warburg: Surface Reactions in Living Cells.

Prof. H. Pfeiffer: Isoelectric Point of Cells and Tissues.

Dr. A. von Muralt and Dr. J. Edsall: Double Refraction in Protein Systems.

Dr. J. H. Quastel: The Mechanism of Bacterial Action.

Other speakers will be: Prof. E. F. Burton, Prof. J. Duclaux, Prof. H. Euler, Prof. H. Freundlich, Prof. H. R. Kruyt, Prof. H. Lundegardh, Dr. P. Lecomte du Nouy, Prof. W. J. V. Osterhout, Prof. Wo. Ostwald, Prof. and Mme. Jean Roche, Dr. Straub, and Prof. T. Svedberg.

SATURDAY, SEPTEMBER 27, 1930.

What's in a Name?

DURING the early days of September the section on Nomenclature of the International Congress of Zoology has discussed at Padua, with live interest and some acrimony, if we may judge from our recollection of the meetings three years ago at Budapest, questions about the naming of animals; and at the same time the British Association for the Advancement of Science has devoted two presidential addresses to a kindred problem. Clearly here is a matter which demands consideration.

It is a happy coincidence that two leading official authorities in the systematic classification of animals and plants, Dr. W. T. Calman, keeper of zoology in the British Natural History Museum, and Dr. A. W. Hill, director of the Royal Botanic Gardens, Kew, should each from his own point of view direct attention to the problems of taxonomy. Although one address supplements the other, both experts meet on common ground in deploring the fact that there is a strong tendency to deprecate the value of taxonomy and to ignore its claims to a fair share of the attentions of scientific workers. "The anatomist, the physiologist, the field naturalist, the student of one or other of the innumerable specialisations of biological science, has always been inclined to regard with distaste, if not with contempt, the work of those whose business it is to denominate, classify and catalogue the infinite variety of living things", says Dr. Calman; and Dr. Hill, echoing the same idea, laments that "we seem somewhat to have failed to attract a sufficiency of able recruits".

What's in a name, that the task of naming should be shunned by potential workers? Names are not what they were. When Linnæus put on a firm footing the binomial system of designating species, he catalogued about 4370 animals. Now the number of described species has been estimated at something in the neighbourhood of three-quarters of a million. The botanists show even less sign of vegetating in this fruitful field, for the recently issued seventh supplement of the "Index Kewensis" contained some 33,000 new specific names. This does not mean that the variety of plant and animal life on the earth is increasing at this extraordinary rate, but it does mean that the technique of naming has become more delicate, that finer distinctions are drawn between species —in other words, that the species of to-day is a different thing from the species of the Linnæan conception.

The result is obvious in the recent developments of nomenclature. In the animal world the old Linnæan binomial is giving way before a trinomial designation, and geographical races are backed by varieties. Botanists have their own specific finesse: their Linnæons are supplemented by Jordanons, the 'compound species' by the 'micro-species' (the latter the units of which the former is made up), and 'hybrid swarms' complicate the story. Now a name should be more than a simple appellation; it should be a symbol of a relationship, and the scheme of names should indicate the system of natural evolution. Whether the new manner of naming properly interprets the variety of form in the plant and animal worlds is a matter which we shall examine in due course, but it has had two harmful effects upon the progress of knowledge. Its complexities and its almost super-meticulous discriminations have put to flight the amateur naturalist, whose kind has in the past taken so great a part in the advance of British science, and it has created groups of specialists, who, retreating within the protective shell of their specialism, tend to see the world of life with narrow vision and to be satisfied with the creation of 'species' irrespective of environment or any other vital influence. Many new species founded upon minute differences and created for single specimens extracted from the herbarium or the museum stores, are cases in point.

The degree of segregation of function to which specialisation has been carried in other branches of science as well as in the taxonomic is a sign of the times. As Dr. Calman puts it, "the Poet of the Breakfast Table, laughing gently at the narrow specialism of the Scarabee, can scarcely have foreseen the day when a university in his own country would have upon its teaching staff an officer named in the university calendar as a 'Drosophilist'". This general movement often ignores the basic necessity of taxonomy, yet it becomes clearer and clearer that specific structure is linked with specific habits and functions, so that the foundation of sound description in whatever line is proper determination of species.

Has the science of classification, then, reached the stage of perfected description of species? It is often said by workers in other fields that the business of naming is a back number; that except in a few odd corners, the inhabitants of the earth have been sufficiently catalogued. The straits to which some systematists are put to define their species, and the perpetual creation and demolition of so-called new forms, give colour to the complaint. If naming is to tell anything of the history of the evolution of forms, it is indeed apparent that in some respects it must revise its methods, or perhaps one should rather say, check the exuberance of some of its devotees. It must be realised that the minute description of all the structural features of an individual or group of individuals is not the definition of a species. The single museum or herbarium specimen, divorced from the story of its habitat and growth, should be regarded as a new type only in extreme cases. Above all, study must be pushed from the laboratory into the field, and analyses of the range of variation normal in an individual, of temporary modifications in form induced by peculiarities of soil, climate, or environment generally, must build a sounder basis for descriptions of phylogenetic significance.

When all this has been done, there may still be something lacking. It has been assumed from the time of Linnæus that form defines the animal or plant. But this convention ignores the many-sidedness of the living organism, and there may be living characters which reveal specific grouping. If we are not prepared to admit physiological species as well as morphological species, at any rate we must admit that stable and well-defined characteristics may elude morphological analysis. Dr. Hill gives some interesting illustrations of the blind spot in morphology. The botanist is unable to separate two forms of the leguminous *Butea frondosa*, but the Indian lac insect feeds on one and will not touch the other. The South African Pentzias are widely distributed on the plains; but while some are eaten greedily by sheep, others are entirely avoided, and still others, usually left untouched, cause unmistakable symptoms of nervous depression when grazed. Yet no morphological difference of any value can be detected between these three forms. In another direction the common mistletoe illustrates the same problem. There is a form of mistletoe which grows on deciduous trees, another associated with fir trees, and another with pine trees; but the seeds of the pine form will not grow on fir or on apple trees, nor will the others sprout except on their own type of host. Morphological identity may conceal physiological diversity. It is significant that morphology alone cannot necessarily solve the problem of relationships. Physiology and chemistry must join hands with structural analysis before the ultimate variations or adaptations can be interpreted.

These points need not be laboured. They make

evident, however, that taxonomy has not yet reached the final analysis. It is not a back number, but in a new spirit it demands from many angles fresh study of characters and groupings. There are still problems to be solved, interesting in themselves, of service in the advance of pure knowledge, and of vital economic value; and the solution of these problems demands not only the best knowledge of the schools, but also the ingenuity of fertile and unhampered minds.

At home and abroad more scientific research workers are required, and more posts adequately endowed for them to occupy. The addresses of the presidents of the Zoological and Botanical Sections of the British Association ought to stimulate interest and recruitment in a branch of scientific work which for the moment and for no very good reason has fallen somewhat out of favour.

Haloes.

Probleme der kosmischen Physik. Herausgegeben von Prof. Dr. Christian Jensen und Prof. Dr. Arnold Schwassman. Band 12: *Die Haloerscheinungen.* Von Prof. Dr. Rudolf Meyer. Pp. viii + 168 + 2 Tafeln. (Hamburg: Henri Grand, 1929.) 11 gold marks.

THOSE who are interested in the optical phenomena of the earth's atmosphere have reason to be grateful to the editors of this valuable series of monographs, for, at no long interval after "Die Dämmerungserscheinungen", has appeared this volume dealing with the luminous rings, arcs, and patches, always beautiful and sometimes remarkably impressive, which are due to refraction and reflection of light by ice crystals suspended in the atmosphere. That these phenomena, which usually receive the general designation of halo, were due to ice crystals was suggested more than two centuries ago, and though the classical memoir by Bravais in 1847 admirably surveyed the knowledge of the time and, for certain phenomena, elaborated explanations which have required no essential modification, there are a number of matters which remain obscure at the present day. The halo of 22° and the associated parhelia (mock suns or sundogs) are the most frequently observed of halo phenomena and are well known to even the casual observer; but there are several other less common manifestations, the occurrence or form of some of which depends on the altitude of the sun (or moon), and there is as yet no unanimity of opinion as to the precise mode of origin of certain forms. On the other hand, the general theory of haloes indicates the possibility of other and as yet unrecorded forms.

The first principal section of the volume under notice is devoted to a general description of the chief halo forms (reference being made to some of the remarkable 'halo-complexes' which have been observed) and to a discussion of observational data, from polar as well as from other latitudes, with intent to reveal the frequency of occurrence of individual or associated forms of halo, and the geographical, annual, daily, and secular variation in frequency. It may be noted in passing that haloes occur more frequently than may be generally suspected, there being on the average one observation about every three days at places in middle latitudes. Certain observational series appear to indicate that there may be a restricted inverse relationship between the frequency of haloes and that of sunspots, but the evidence from other series is conflicting. It is very evident that the non-comparability of sets of observations is responsible for the inconclusive or divergent results of several of the statistical studies which have been made from time to time. The observational data are not published according to a uniform scheme, and the observations are made with varying degrees of intensiveness, the waxing and waning of individual or general interest in the phenomena being reflected in the observations.

The first section of the work concludes with a discussion of the relationships with cloud and cloudiness, and with the general weather situation. There is some evidence that in Holland the ordinary mock suns and the circum-zenithal arc, both of which are attributed to crystals floating with the principal axis vertical, occur definitely more frequently behind than in front of a depression: that is, presumably more frequently in old than in new cirrus cloud. The age-long belief in the value of haloes as prognostics of stormy or cold weather seems to receive no support when subjected to critical investigation, but it must be admitted that the number of really critical investigations of this matter is insufficient.

Hexagonal ice crystals of elementary form—columnar or laminar prisms, alone or in association, and with or without pyramidal caps—are regarded as the refracting and reflecting agents necessary to the production of haloes, and it is obvious that all physical circumstances which in any way determine the form and behaviour of ice crystals in the atmosphere, usually at the cirrus level, are relevant to any complete study of the phenomena. The dependence of form of crystal on temperature and on the rate of crystallisation; the size of effective

crystals; the nature of the motion of the crystals through the air; the effect of the quantities of crystals present; the brightness and polarisation of haloes; diffraction effects; the optical properties of ice; and the all-important rôle of refraction at minimum deviation, are treated in the second section, which deals with the general foundations of halo theory. By the very nature of the problem it is extremely seldom that any direct observation is possible on the form, size, and character of motion of ice crystals which produce a given halo. Much of our knowledge of these matters has been acquired indirectly and by analogy. Experiments with models in the form of typical ice crystals have shown that in general they tend to fall in such a way that the resistance to motion is a maximum. This, an important point in the explanation of the production of certain forms of halo, is in direct opposition to the assumption made by earlier workers. Emphasis is laid on the desirability of investigation of the physical factors determining the form and equilibrium setting of ice crystals, of the question of oscillation as distinct from rotation of crystals, and on the need for quantitative observations on the brightness and polarisation of haloes.

Nearly one-half of the volume is occupied with the discussion of the several forms—the haloes of 22° and 46°, the various arcs of contact associated with these haloes, the various parhelia, the parhelic circle, the circum-zenithal and horizontal arcs, the anthelion, the paranthelia, sun pillars, and others. A detailed survey is given of the circumstances of production of individual forms, of their characteristics and variations, and of the views of the chief workers in this field of inquiry. In this section, as elsewhere, mathematical expressions are not derived or quoted, but where necessary the results of such analysis are quoted and compared with observational data, and there are diagrams both of halo forms and of the paths of light rays through ice crystals. Certain unusual haloes are noticed, but the author does not mention that some ten years ago Besson showed that the very rarely observed haloes of about 8°, 17°, 19°, 24°, and 32° radius may all be attributed to a crystal with pyramidal ends, the pyramidal faces being inclined at 25° 14′ to the principal axis; and that, a little later and independently, Humphreys made the same suggestion but gave, from the results of X-ray analysis of ice, 24° 51′ as the value of the angle.

Useful recommendations on the technique of observation, both visual and photographic, are contained in the final chapter. There is a numbered bibliography of about 250 entries and the reference numbers are employed liberally throughout the text.

The author is heartily to be congratulated for giving us, within rather less space than is occupied by the corresponding section of "Meteorologische Optik" by Pernter and Exner, so complete an account of haloes; for keeping in the forefront the general and particular problems involved, and for succeeding so admirably in his aim to produce a book which will appeal to those outside a small circle of specialists in the subject. One regrets that there is no work in the English language with which Dr. Meyer's monograph may be appropriately compared.

H. W. L. A.

The Art of Geological Map-making.

Methods in Geological Surveying. By Dr. Edward Greenly and Dr. Howel Williams. Pp. xvi + 420. (London: Thomas Murby and Co.; New York: D. Van Nostrand Co., 1930.) 17*s.* 6*d.* net.

THE authors tell us that one of the earliest, if not the first, to suggest the making of a geological map in Britain was one John Aubrey, who lived in the seventeenth century. We are also told that he was described by a contemporary as "a shiftless person, roving and magotie-headed, and sometimes little better than crazed"; whether because or in spite of his suggestion is not stated. One knows, however, that, even in these enlightened days, geological surveyors are often not recognised as such. Their hammerings and apparently aimless wanderings cause wonderment and comment, the latter sometimes caustic.

It seems that, in Great Britain, the functions and, in fact, the very existence of a Geological Survey are not so widely known as is desirable, at least to the general public. The appearance of a book which, among other things, directs attention to this branch of scientific activity is therefore welcome.

The senior author, Dr. Edward Greenly, received his early training as a member of the Scottish staff of the Geological Survey of Great Britain. Afterwards he pursued his detailed survey of Anglesey for twenty-four years, with results well known. Dr. Howel Williams, in addition to his work in Wales, has taken part in pioneer surveying in the United States. Their combined experience well fits them for the task they have undertaken.

The manual is intended for those desiring to know how geological maps are made, and is not concerned with their interpretation. The authors maintain as the principal aim of geological mapping that it should be an end in itself rather than a means

to an end. To us this point of view seems a little over-stressed. Surely the production of a map, however important, must always be a corollary to the geological survey undertaken first of all to gain knowledge, be it scientific or economic, of the geology of a country.

While primarily intended for the use of those who have the advantage of large-scale topographical maps, the book also deals with pioneer and reconnaissance mapping.

Part I. is devoted to introductory and historical matters only. Though full of interest, it is somewhat surprising to find that it occupies one-third of the text. That this is so is less astonishing when, for example, we discover that two and a half pages are solely occupied with the etymology of one word—'chart'. In addition to the evolution of geological cartography, the history and methods of construction of topographical maps are discussed here.

There is much in Part I. to repay the general as well as the geological reader, especially in these days of motoring and cheap maps. Few give a thought to the care and labour involved in their production. It cannot, however, be maintained that much of Part I. is essential to the stated objects of the book.

Part II. consists of a detailed exposition of the methods of mapping employed by the authors and others in Great Britain and elsewhere. It includes notes on the preparation and care of maps, note taking, specimen collecting, and other incidentals. In addition, there are chapters on the use of surveying instruments. The methods elaborated seem to be thoroughly sound, and we cannot offer any major criticisms. Each individual mapper will incorporate his own idiosyncrasies in his own maps, but if he bases his field work on the system here advised he will not go far wrong.

Appendix I. includes an explanation of the frontispiece. This is a poorly reproduced facsimile of one of Dr. Greenly's field maps. Apart from poor reproduction, we should have expected something better after reading the text.

There are also three tables of useful mathematical constants, and the book concludes with an extensive bibliography.

The difficulties of geological surveying are summed up in the statement that while a topographical surveyor maps what he sees, the geologist, as often as not, must map what he cannot see. The authors therefore recommend caution at all times, and attention to detail. They rightly insist that on field maps observations should in all cases be distinguished from inference. There is a not inconsiderable number of geologists who are in the habit of indulging in sporadic bouts of field work, more for the purpose of obtaining results for publication than with any idea of producing a worth-while map. Considerations of time may militate against their acquiring the knowledge of field technique that can only come from prolonged work in the field. To them especially, and also to students in general, the counsel of perfection expounded by the authors is specially recommended.

"Methods in Geological Surveying" contains much that is discursive. If limited to matter essential to its scope, it might have been reduced very considerably in size and, more important, in price. Then, however, there would have been left only the bare bones of a text-book. As it stands the book is eminently readable, and may, we think, be perused with pleasure and profit by all geologists.

Bacterial Housekeeping.

Bacterial Metabolism. By Marjory Stephenson. (Monographs on Biochemistry.) Pp. xii + 320. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1930.) 18*s.* net.

THE chemical action of bacteria (and other micro-organisms) has always aroused great interest for two reasons. The weight of material which undergoes change frequently stands in striking disproportion to the weight of the organisms which provoke the change, and the products, in contrast to the few simple end substances formed by the oxidation of food materials in the animal body, are diverse in kind and often complex in nature. The clue to the explanation of these phenomena lies in the fact that bacteria and many other micro-organisms possess, in addition to the aerobic mode of life in which food materials are oxidised by the aid of atmospheric oxygen, the faculty of acquiring the special compounds requisite for growth and the energy for both growth and maintenance by an anaerobic process. In this atmospheric oxygen is not involved, since it consists in producing a rearrangement of the atoms of the food materials so that the resulting compounds, often of a highly complex nature, contain less energy than those from which they have been formed. This process, known generally as fermentation, results, as was first pointed out by Lavoisier, in the transference of oxygen and hydrogen from one atom to another in such a way that one part of the molecule becomes oxidised and another reduced,

the bonds between the carbon atoms being often simultaneously broken, so that a number of smaller molecules are produced.

Peculiar interest also attaches to the autotrophic bacteria, which, as the author points out, are, like green plants, independent of other living beings and are, moreover, independent of the energy of light, since they are able to utilise the energy liberated by oxidation of various inorganic materials (for example, sulphur or a ferrous salt) for the conversion of carbon dioxide into assimilable carbon compounds.

The present work is one for which biochemists have long been waiting and it will be received with gratitude. The predominant interest attached to bacteria as the prime causes of disease has overshadowed the study of their general physiology, and, as the author says in her preface, it is indeed "time that an attempt should be made to arrange the scattered data in order to appraise our knowledge of bacteria as living organisms".

This has been very effectively accomplished, and the successive chapters, which cover the whole field of bacterial metabolism, all show evidence of diligent search and wise selection.

As might be expected, the chapter on respiration is of particular interest and presents an extremely interesting picture of the work of the Cambridge School, in which the author of the book has herself taken such an important part.

It has, of course, not been found possible to deal with equal thoroughness with all the subjects discovered; thus the section on the death-rate, in which reference is made to the large subject of disinfection, might usefully have been expanded.

An appendix is provided dealing with practical methods, and the work concludes with a most valuable bibliography, extending to thirty pages.

ARTHUR HARDEN.

The Comparative Anatomy of the Brain.

The Evolution of the Nervous System in Invertebrates, Vertebrates and Man. By Dr. C. U. Ariëns Kappers. Pp. vii + 335. (Haarlem: De Erven F. Bohn, 1929.) 8·75 g.

WHEN the International Brain Commission met in 1905 at the Royal Society's rooms in London, it recommended the establishment of a central institute for brain research in each of the countries represented. While most of the representatives regarded this resolution as the expression of a pious wish not likely to be realised, the Royal Academy of Sciences in Amsterdam set to work to found such an institute as the Brain Commission recommended and placed Dr. Ariëns Kappers in charge.

It is no exaggeration to claim that this enlightened course made Amsterdam the chief centre for the investigation of the comparative anatomy of the brain, not merely for Holland but also for the whole world. During the War, the issue of three large volumes on the comparative anatomy of the nervous system in vertebrates and invertebrates by Dr. Ariëns Kappers and Dr. Drooglever Fortuyn, providing as they did the most impressive collection of data yet made available on this subject, revealed the great significance of the work accomplished during the first ten years of the Brain Institute's work, and set the seal of success upon the Royal Amsterdam Academy's enterprise.

The first half of the valuable book that has just been issued in English may be regarded as a concise and generously illustrated summary of the large treatise, brought up-to-date. Like all Dr. Ariëns Kappers's writings, it is a simple and lucid statement of the present state of knowledge, in which the often conflicting views of different workers are fairly and fully stated, along with the solid background of Dr. Kappers's own observations. It is a general survey of the facts relating to the nervous system as a whole in invertebrates and vertebrates, and especially the comparative anatomy of the cerebral cortex, striatum, thalamus, cerebellum, medulla oblongata and spinal cord, together with a useful account of the evolution of what Dr. Kappers calls the 'metabolic tissue' of the central nervous system.

This section of the book will be of particular value to students of comparative anatomy and psychology in providing them with a brief and easily understood survey of the whole field of comparative neurology.

The latter part of the book is a comprehensive survey of the literature, and Dr. Ariëns Kappers's original observations, on what he calls the anthropology of the brain, "written in the hope that it may increase the interest in this much neglected field and stimulate further research". It gives a succinct and well-illustrated account, with an excellent bibliography, of the work which has been accomplished in the study of endocranial casts of the extinct members of the human family and of the actual brains of the various living races of mankind.

The volume is a most useful book of reference, with an exceptionally full index.

G. ELLIOT SMITH.

Our Bookshelf.

Northern Rocky Mountain Trees and Shrubs. By Dr. J. E. Kirkwood. Pp. xvii + 340 + 35 plates. (Stanford University, Calif.: Stanford University Press; London: Oxford University Press, 1930.) 35*s*. net.

DR. JOSEPH EDWARD KIRKWOOD, the author of this work, made a life study of the flora of the northern Rocky Mountains, but, unfortunately, he died suddenly in August 1928, whilst the present book was in course of preparation. The title indicates the scope of the work, and the region included embraces the country from the Yellowstone Park, north and north-west through Montana and Idaho and the Canadian Rockies, covering the various ranges and the closely adjacent plains. The limitation of area naturally excludes from this work many of the well-known trees and shrubs of western North America, but in an introduction describing the area and the peculiar distribution of various genera and species, we find that 79 genera and 248 species are found in the region under notice. The introduction is ended by a key to the 27 families concerned. *Salix* is the most prolific genus in species, for some 51 are described.

Beginning with Pinaceæ, the various families with their genera and species are then passed in review. A family description is first given with a key to the genera, then follows a description of a particular genus with keys to the species and good specific descriptions, with excellent illustrations of shoot, leaf, flower, fruit, and seeds. Some eighty-seven figures of this description are included in the 340 pages to which the book runs, whilst there are thirty-five full-plate photographs. The descriptions are in non-technical language and should not create difficulties for the person who has little or no botanical knowledge, but in some quarters difficulties may arise through the splitting up of genera. Thus, for the well-known shrub *Spiræa discolor* Pursh, the name of *Holodiscus ariæfolius* Greene is used. The generic name of *Neillia* gives place to *Opulaster*; *Rubus parviflorus* Nutt. is described as *Bossekia parviflora* Greene, and *Spiræa millefolium* Torr. as *Chamæbatiaria millefolium* Maxim. Where this division of genera occurs it would have been an advantage had the well-known names been bracketed with the ones used.

A Study of the Induction Motor. By Dr. F. T. Chapman. Pp. xvi + 289. (London: Chapman and Hall, Ltd., 1930.) 21*s*. net.

THE induction motor is one of the most useful mechanical slaves that man has ever invented. It is deserving, therefore, of the most careful study, and engineers will welcome a good exposition of the theory. They will find it in this book. Dr. Chapman was the designer of alternating current machinery to Messrs. Greenwood and Battey of Leeds. He was afterwards senior lecturer and superintendent of the testing department at Faraday House, London. He is now an inspector of technical colleges for the Board of Education. His experience therefore qualifies him in every way for writing a treatise on electric motors, and in particular of the induction motor, of which he has always made a special study.

The book contains a great deal of original matter now published for the first time. The student will welcome the author's method of finding the fundamental equations and developing the circle diagram on the assumption that the motor may be replaced by a stator and rotor made from magnetic material of infinite permeability, the air gap being bounded with smooth unbroken surfaces. Afterwards the length of the air gap used in the formulæ is corrected in order to take into account the presence of slot openings and the saturation of the iron.

The author shows that the theory can be readily developed by simply using algebra and geometry. Those who think that there is something specially powerful in vector algebra, which the reviewer does not, can easily convert Dr. Chapman's proofs into that form. Several firms make electric motors only, four or five of which are required for every cine-sonoro (talkie). This book will be of great use for designers.

Photographic Printing Processes. By Capt. Owen Wheeler. Pp. xvi + 260 + 6 plates. (London: Chapman and Hall, Ltd., 1930.) 8*s*. 6*d*. net.

THE average amateur is generally content to confine himself to the practice of one or two photographic printing processes. He is not aware of the many other processes, varied in nature and giving beautiful results, which will repay his attention; to some extent the same is true of the professional photographer. To both these classes this book should make an appeal. Capt. Wheeler embodies largely his own extended experience in the description of processes ranging from print-out, through bromide, carbon and carbro, gum-bichromate and its variants, dye-printing, etc., to colour printing. The details given are such that it should be easy for novices in a particular process to go straight ahead and acquire proficiency. The scientific principles involved are not discussed, and only the simplest chemical terminology is used.

Rasa-Jala-Nidhi: or Ocean of Indian Chemistry, Medicine and Alchemy. Vol. 3. Compiled in Sanskrit by Bhudeb Mookerjee. With English translation by the Author. Pp. xxxvi + 390. (Calcutta: The Author, 41A Grey Street; London: Luzac and Co., or Arthur Probsthain, 1930.) 6 rupees.

MR. MOOKERJI is a medical practitioner who is publishing a series of volumes on the pharmacopœia of drugs prepared from minerals, based on ancient sources. His work is of interest to students of Indian chemistry and medicine, although it is sometimes without apparent logical arrangement and contains a great number of names of plants and materials transcribed without the elucidation necessary for European readers. The present volume deals with the metals, gems, alkalis, salts, poisons, oils, and fermented liquors. The Sanskrit text is given, followed after each section by an English translation.

Letters to the Editor.

The Observation of the Opposition of Eros.

IN *Astronomische Nachrichten*, No. 5722, is published an article "Zur Beobachtung der Eros-Opposition", by Prof. Hartmann, in which certain recommendations are made to those who will be co-operating on the observations of Eros around the forthcoming opposition.

As chairman of the Solar Parallax Commission of the International Astronomical Union, I desire to state that some of these recommendations cannot receive the support of the Commission. Prof. Hartmann recommends that observations should be limited to the period 1931, Jan. 1 to Feb. 26, and that they should be secured at intervals of four days throughout this period, except that from Jan. 25 to Feb. 6—when the parallax of Eros has practically its maximum value—observations should be secured daily. Southern observers are recommended to obtain daily observations, in addition, on Mar. 14–18, when Eros is near a stationary point. He further recommends that observations should be secured at large east and west hour angles only, and states that observations on the meridian, between a northern and southern observatory in co-operation, are not to be recommended in view of the possibility of observations being frequently secured at one of the co-operating observatories and not at the other. He considers that the advantages of the co-operative and practically simultaneous observations—elimination of the errors of positions of comparison stars and of the ephemeris of Eros—do not outweigh the loss of weight in parallax factor as compared with observations by the east-west method.

The co-operative programme of observations has for its purpose the accurate determination of (1) the solar parallax, (2) the mass of the moon and other related constants. In so far as (1) is concerned, limitation of observations to the period recommended by Prof. Hartmann would undoubtedly provide adequate weight for the derivation of the solar parallax, if weather conditions were satisfactory throughout the period.

It must be remembered, however, that observing conditions at this time of year at most places in the northern hemisphere are not generally satisfactory, and that long spells of cloudy or unsettled weather are possible. By the end of February Eros will have moved too far south to be accessible to most of the co-operating observatories in the northern hemisphere, and if observations have been unduly interfered with by bad weather, it will then be too late to obtain additional material. From this point of view, it is desirable that northern observatories should secure observations before Jan. 1. From the middle of November the parallax of the planet is greater than 20″, increasing to nearly 40″ at the end of December; observations during this period can add appreciable weight to the derivation of the solar parallax. Observers in the southern hemisphere are more fortunate in that Eros is first accessible when its parallax is near its maximum value, and the extent to which observations need be continued as the parallax decreases will be conditioned by the weight of the material already accumulated.

As regards (2), observations over as long a period as possible are required in order to cover a number of lunations and so enable the lunar equation term to be more satisfactorily disentangled from the errors of the ephemeris of Eros. In this connexion, the experience of Mr. Hinks on the discussion of the observations secured at the 1900–1901 opposition (when the maximum parallax was only 28″) may be recalled (*M.N.R.A.S.*, **70**, 63, 1909): "For the parallax determination the observations made after Christmas 1900 had very little weight. But, on the other hand, it will appear that the part of the series most valuable for the determination of the mass of the moon is the latter half, from the middle of December to the end of February. It is fortunate, therefore, that some observers persevered throughout the unfavourable months of January and February, 1901, after those whose main interest was the solar parallax had stopped work." Dr. Jackson (*M.N.R.A.S.*, **90**, 742, June 1930) has recently directed attention to the discordance between the observed and theoretical values of the constant of nutation and the importance in this connexion of a determination of the mass of the moon. It is hoped that all observers will plan their observations with the view of providing material for the determination of the mass of the moon as well as of the solar parallax.

With regard to the co-operative observations between northern and southern observatories, these are not being planned to the exclusion of observations at large hour angles, but will be in addition to them. Observations obtained at one observatory, when conditions are unfavourable at the other, need not be wasted, as such observations can be utilised in connexion with the derivation of the errors of the ephemeris of Eros and of the mass of the moon. On the other hand, the simultaneous observations at the two observatories are ideal for the derivation of the solar parallax, being entirely independent of errors of comparison star places and of the ephemeris of Eros.

A Simple Lecture Demonstration of Lattice-'Planes' in Two Dimensions.

STUDENTS frequently find some difficulty in picturing lattice-planes in X-ray crystallography, and in their elucidation, apart from isometric drawings and models of crystal forms and lattices, recourse is usually made to drawings of a two-dimensional lattice. I venture to hope that the following simple demonstration may be of service to those who have to lecture on this subject.

The device is an adaptation of the lecture-demonstration of optical diffraction patterns projected on a screen across the lecture theatre—a demonstration which is not so often shown as it deserves to be. By means of a condensing lens, the light from an arc is focused in front of a narrow slit, so that the length of the slit is filled with light, and a thin pencil of light passes beyond the slit to the diffracting object, placed (say) one foot away from the slit. In these circumstances, beautiful diffraction patterns of wires, straight-edges, needle-points, etc., can be readily observed by the audience on a screen placed several yards away. It is often advantageous to tilt the screen and so broaden the fringes.

If, in this arrangement, the diffracting object is replaced by an ordinary square-mesh wire gauze arranged normally to the incident light, it becomes

an effective lecture-demonstration of lattice-' planes ' in two dimensions. Assuming one set of wires of the gauze to be vertical and parallel to the slit, only the vertical wires cast sharp shadows on the screen, the horizontal wires being ineffective because each point of the slit casts its own shadow, as it were, of each point of the gauze. We thus see on the screen a series of vertical line-shadows, with their accompany-

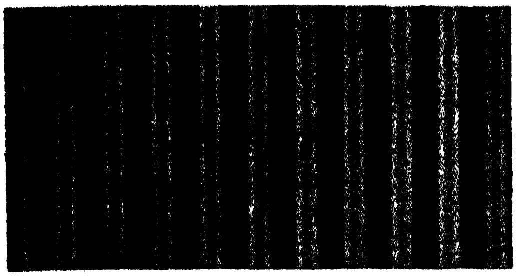

FIG. 1.—(1·0)-' Planes '.

ing diffraction patterns, often very beautiful, especially at distances of several yards. These vertical lines (Fig. 1) represent the (1·0)-rows (' planes ') of the two-dimensional lattice, in which the points of intersection of the vertical and the horizontal wires are the *units* of the lattice. If we turn the slit through 45°, the diagonally elongated shadows of the units give rise to well-defined linear shadows on the screen, representative of the (1·1)-' planes ' in the lattice (Fig. 2). For various intermediate positions of the slit, quite a number of such well-defined, inclined shadows of the units can readily be seen on the screen, running parallel to one another. Moreover, the intensity and distance apart of the shadows increase, almost without exception, with the number of units per unit length in the relevant ' plane '. Fig. 3 reproduces the pattern which corresponds to the (3·1)-' plane ' of the gauze, and I have succeeded in photographing several others, but the three figures here shown will suffice to illustrate the generality and effectiveness of the demonstration.

Only the simpler figures are suitable for demonstration to a seated audience, but by viewing the screen

FIG. 2.—(1·1)-' Planes '.

close up, I have had no difficulty in observing and identifying the figures corresponding to the following ' planes ': (1·0), (7·1), (6·1), (5·1), (4·1), (3·1), (2·1), (1·1), (3·2), (5·3), (4·3), (5·4), (6·5). Other weak figures have been observed, but not identified with certainty. For all the gauzes I have examined, the figure corresponding to the (2·1)-' plane ' is exceptional in its behaviour. Instead of giving bold black shadows, it gives fine-line and weak shadows, correctly spaced, and generally accompanied by a weaker component on either side of each of the main shadows. I have not succeeded in explaining why the (2·1)-' plane ' behaves in this way.

The experiment can be performed with gauzes of different size of mesh, but the most satisfactory results have been obtained with a gauze with wires about 1/3 mm. thick, and of spacing about 1·3 mm. The spacing of such gauzes usually differs in perpendicular directions by several per cent, and with the one used in taking the photographs here reproduced the angle corresponding to the (1·1)-row was calculated to be 42° 35′ (instead of 45°); the actual amount through which the slit, mounted on a circular scale, had to be rotated from the vertical to obtain this figure most clearly was found to be 42° 39′—a very satisfactory agreement. Perforated zinc or copper gauze, with hexagonal pattern, can also be effectively used in the demonstration, and generally shows a periodicity in the patterns and intensities obtained, owing to the periodic grouping in the spacing of the perforations. Good results are also given by the use of positive or negative plates obtained by photographing point-row lattices or squared paper with prominent black lines on a white background, especially when a permanent set of ' grids ' is required for demonstration purposes, as different types of lattice can readily be drawn and photographed. In general, however, ordinary square wire gauze is a convenient and ready-at-hand lattice, sufficient for most purposes.

FIG. 3.—(3·1)-' Planes '.

The accompanying photographs were obtained by exposing bromide paper on the screen, placed about six feet beyond the gauze, and taking bromide paper positive contact prints of these negatives, using a ' Lumino-phor-Leuchtfolie ' as the source of contact illumination.

In conclusion, it may be of interest to direct attention to an interesting optical effect obtained with squared paper—black lines on a white surface. On looking at this surface perpendicularly, and moving the eye to different parts of the surface, the intersections of the black lines appear to have white centres, and one gets an impression of two perpendicular sets of white diagonal lines over the surface—the (1·1)-' planes ' of the lattice. The effect is more pronounced by observing the squared paper (card is preferable) at grazing incidence, and in the appropriate orientation of the card, when one has no difficulty in observing ' white lines ' crossing the card in the directions of the (1·1)-, (2·1)-, and (3·1)-' planes '.

Chromosome Behaviour of Triploid Œnothera.

IN two recent issues of NATURE, Darlington [1] and Gates [2] have entered into a discussion of synapsis in triploid Œnotheras. The root of controversy lies in the novel observation and interpretation of Catcheside [3] that a continuous ring of 21 chromosomes was formed in a triploid plant. Having been engaged for the past two years in an investigation dealing with the genetics and cytology of triploid Œnotheras, I

have naturally focused my attention on all published accounts of polyploidy, particularly those which deal with chromosome behaviour in triploids. At the suggestion and under the guidance of Prof. G. H. Shull I undertook the studies of triploid Œnotheras, the origin of which he has described in a recent paper.[4] Fifteen triploids were turned over to me in the fall of 1928 and their cytology was studied. I have since then made cytological analyses of buds of triploids in the summers of 1929 and 1930. The triploids studied in the last two years have all been derived from pure *Œ. Lamarckiana*. As the chromosome behaviour in triploid Œnotheras has become an issue of lively interest, I report here such observations as are pertinent to the fundamental point under discussion. My observations were based on paraffin sections stained with Heidenhain's iron-hæmatoxylin and on smear preparations of pollen mother cells stained with iron-Brazilin.[5] My microscopic preparations have been examined both by Prof. E. G. Conklin, under whose supervision I have acquired my cytological technique, and by Prof. Shull.

In microsporogenesis of triploids, it can be frequently observed that rows of pollen mother cells in different phases of mitosis occur in the same bud. Not infrequently also, pollen mother cells in various stages of cell divisions are found in a single anther segment. This condition enables one to trace with accuracy the various phases of meiosis. Microscopic slides, particularly the paraffin sections, are now available which show the stages from early presynizesis up to the reconstitution of daughter nuclei. I have observed that the threads issuing from the synizetic knot are single in Nature, as evidenced by the presence on them of a single row of chromomeres. In the second contraction stage the pachytene threads also remain single and later the chromosomes are formed as single segmented bodies invariably connected end to end, and undoubtedly conjugation has occurred in telosynaptic fashion. This arrangement of chromosomes is in many instances, especially the Y-shaped (trivalent) chromosomes, in agreement with the earlier account of Hakansson,[6] and it confirms some of the observations which were made by Darlington [1] on Catcheside's slides.

In my triploids are shown two or more chains open or closed to form rings, Y-shaped trivalents, unpaired chromosomes, and single pairs of chromosomes in the form of rings. These ring pairs generally encircle the long axis of the chain. All prophase spiremes seem to be characterised by the presence of trivalents which are formed in various shapes, the predominating one being Y-shaped. The open chains are often branched at one end with from 1 to 2 chromosomes in a branch. In no case could it be observed or even inferred that the 21 chromosomes were all united in a single circle. Paraffin sections and uncut cells of smear preparations gave essentially identical results. The various types of chromosome rings and configurations persist in the formation of multipolar or bipolar spindles at meiotic metaphase. At metaphase plate they aline themselves in the characteristic zigzag manner of other Œnotheras, and the plate shows two or more circles or chains interlacing with one another. In anaphase the chromosomes seem to orient themselves at haphazard with respect to the poles to which they move. In this chromosome separation two members composing the trivalent move to one pole and the third to the other.

It is not within the scope of this short account to discuss the interpretations of the chromosomal configurations here described. Suffice it to put on record at this time that the chromosome associations, especially the trivalent forms, are quite characteristic of meiosis in Œnothera triploids. A fuller preliminary account of these investigations is appearing in the *American Naturalist*.

Moving Striations in Positive Column in Rare Gases.

IT is now well known that the visually observed uniform positive column in rare gases is in reality discontinuous, consisting apparently of a series of uniformly spaced moving striations which travel from anode to cathode.

I have pointed out the following facts in connexion with this phenomenon:

1. The light emitted does not exhibit the Doppler effect even when observing the fastest flashes moving up to 10^6 cm./sec. at the lower pressures (*Proc. Camb. Phil. Soc.*, Jan. 1925).

2. At any particular gas pressure there are at least four types of 'flash' which change one to another in a definite manner (*Proc. Leeds Phil. Soc.*, 1930) with changing current, being all independent of external inductance and capacity.

3. For one type of flash the velocity in the body of the tube is approximately proportional to the reciprocal of the pressure and is little dependent on current and tube potential (see, however, 2).

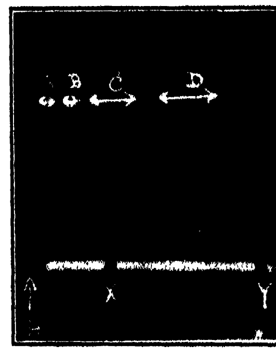

FIG. 1.

4. The current variations in the circuit are roughly about one per cent of the whole—an interesting wave form being associated with this current variation.

I have now formed the opinion that there is a good deal to be said for supposing this phenomenon to be due to a regular sequence of dark spaces travelling at constant speed in a uniform positive column away from the anode. It is clear that such a hypothesis would be in conformity with 1 and 4 above.

An additional experiment which I have just performed attempts to follow the 'flashes' right up to the cathode—which was a dull emitting lime-coated filament placed on the axis of a quartz tube.

The photograph here reproduced (Fig. 1) is of the discharge in argon. The intense white line XY is the uniform positive column photographed directly, punctuated at X and Y by two obstacles 10 cm. apart for reference purposes. On the left at H is an isolated button of light, the negative glow surrounding the cathode. The Faraday dark space is just to the right of H, the anode being out of sight on the extreme right.

Above XY is the photograph on the same plate of the same discharge viewed in a mirror rotating with axis parallel to the tube.

The inclined white streaks are the hitherto named moving striations. Their steepness is a measure of their speed. It will be observed that in the region

above XY—away from the external electrodes—their speed is constant, as shown by the constancy of D wherever taken in this region. Nearing the cathode, however, the separation shrinks to C, then to B, the striations approach closer to each other, lose speed, but, it is noticed, never cross the Faraday dark space, the edge of which they approach in an asymptotic manner. It is important to notice that at the instant one striation has merged its identity in the edge of the Faraday dark space its successor is a distance behind of B equal to A, the Faraday dark space width.

The following table shows the approximate equality of these two distances at different gas pressures :

Photograph number.	Faraday dark space length (A in photo).	Travelling dark space length (B in photo)	Travelling dark space length in body of tube (D in photo).	Pressure in Pirani gauge.
7	0·44	0·54	1·76	20·4
18	0·67	0·67	3·30	18·0
14	1·27	1·34	3·34	10·5
12	1·39	1·39	3·90	9·7

The numbers in the pressure column are the voltmeter balance readings in the usual Pirani gauge circuit and are only included to indicate the trend of pressures employed. R. WHIDDINGTON.

Aucuba or Yellow Mosaic of the Tomato: A Note on Metabolism.

THE metabolism of tomato plants infected with aucuba mosaic disease is being studied at the Cheshunt Experimental Station, and a number of interesting results have been obtained. The following appear to be fairly well established under the conditions of our experiments :

1. In the early stages of infection, the removal of starch from the leaves of a plant placed in the dark is greatly accelerated except at the points of infection, which show a marked local inhibition of starch removal, often surrounded as a transient phase by a zone of accelerated removal. At this stage starch formation in the light does not appear to be affected. The local inhibition is followed at a later stage, often about fourteen days, by the removal of starch over a larger area of the inoculated leaf, slight yellowing of the chlorophyll, and a failure to form starch over this area in the light.

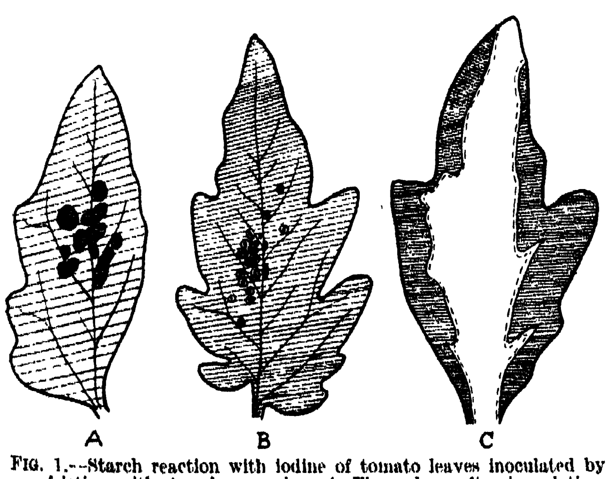

FIG. 1.—Starch reaction with iodine of tomato leaves inoculated by friction with Aucuba mosaic. *A*. Three days after inoculation, kept in greenhouse, tested 9.30 A.M. *B*. Four days after inoculation, kept in dark fifteen hours before testing. *C*. Fourteen days after inoculation, kept in greenhouse, tested 2 P.M.

2. The acidity of an aqueous extract of infected leaves sampled at dawn, that is immediately after loss of starch, is greater than that from healthy leaves.

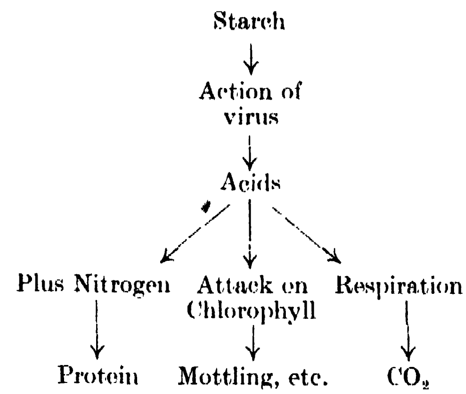
3. Local absence of starch in the leaves, even during the day, appears to precede the appearance of mosaic symptoms.

4. The freshly discoloured chlorophyll appears to react with copper salts, regenerating a green colour.

5. At a later stage of infection, some days or weeks after typical mottling has appeared, a marked accumulation of starch is found in parts of the infected leaves and complete absence in other parts.

6. No definite evidence has yet been obtained as to the relative respiration rates of infected and healthy leaves.

While not desiring to attach undue importance to these results, we venture to suggest the following sequence of metabolism :



This view agrees with all the observed facts as we know them, such, for example, as the different type of winter and summer symptoms, the effect of nitrogen, darkness, and other factors on infected plants.

While much of the work must be repeated under more critical conditions, the above results appear of sufficient interest to be recorded at this stage.

Photographic Sensitisers for the Infra-Red.

A STATEMENT which has been circulated recently (compare NATURE, Aug. 9, p. 218) that the late developments in the technique of infra-red photography have come largely from the needs of the motion picture industry is not accurate, and I think it is worth while to have the record correct.

The making of sensitising dyes for the extreme red seemed to have reached a limit about 1907 with the discovery of dicyanine, and no great progress was made until Adams and Haller at the Bureau of Chemistry in Washington discovered kryptocyanine in 1919. The Bureau of Chemistry was at that time working on sensitising dyes with the general view of making improvements in the preparation of dyes for photographic purposes. Kryptocyanine was utilised by W. H. Wright for his photographs of the Yosemite Valley from Mount Hamilton and later for his photographs of Mars. Its first use in the motion picture industry was by J. A. Ball, who used it for sensitising motion picture film for making imitation night scenes.

Kryptocyanine was not of much value in spectroscopy, its sensitising power being limited to the region below 8000 A., in which region dicyanine was already known to be effective.

Improvements in methods of sensitising with kryptocyanine have now made aerial photography possible with it, and the photograph of Mount Ranier at a distance of 227 miles referred to in the note in NATURE was made on kryptocyanine sensitised film.

In a preparation of kryptocyanine, Dr. H. T. Clarke in 1925 found another dye to be present, which was separated and found to have sensitising power for the extreme infra-red. The name of neocyanine was given to this dye, and it is by the use of neocyanine that the advances in spectroscopy have been made. The discovery of neocyanine had thus nothing to do with the demands of the motion picture industry. It was an accidental discovery resulting from the manufacture of kryptocyanine, which was being used chiefly in miscellaneous scientific work. The maximum sensitising power of neocyanine is at 8300 A.; its sensitising power begins to fall off rapidly at 9000 A., but with long exposure through screens, spectra can be photographed beyond 11,000 A. Since its discovery, improvements have been made in the use of the dye, and modifications of it have been made which are much better for sensitising than that originally produced. A great deal of research has also been done in the hope of finding other sensitisers for the infra-red, both before and since the discovery of neocyanine, but up to the present, no dye has been found which is more effective for the infra-red region than neocyanine. Vitamin Content of Marine Plankton.

THE appearance of the letter in NATURE of Sept. 13, by J. C. Drummond and E. R. Gunther, on the vitamin content of marine plankton, simultaneously with the résumé on p. 423 of the same issue, of the paper by G. Belloc, R. Fabre, and H. Simonnet on the study of plankton sterols, stresses the importance of a knowledge of the vertical distribution of plankton animals in the sea. It is a general rule that most of the plankton animals in Plymouth waters in sunny weather during April, May, and June live at depths below 10 to 15 metres, thus presumably avoiding the layers in which irradiation is likely to take place. In July, however, a definite change comes over the plankton, certain species previously only to be found in the deeper layers becoming abundant right up to the surface itself; this condition persists throughout July, August, and perhaps September. This seems significant in view of Belloc, Fabre, and Simonnet's findings that the sterols collected in July were found to be biologically active, whereas those collected in April only acquired biological activity after irradiation.

Mortality amongst Plants.

ON the Cretaceous plateau that occupies so much of East Devon (800 ft.-900 ft.) beech trees flourish in considerable numbers. The roads crossing the upland are separated from the adjoining enclosures by massive earth banks that are quite remarkable for their breadth and solidity, some being upwards of twelve feet in breadth and six to eight feet in height. On these banks beech trees usually grow, and in some instances form a continuous avenue. Between the roads and the banks are shallow ditches, and in the late spring the bottoms of these ditches are completely green with the first true leaves of seedling beech. None of these come to maturity, as they are browsed off by rabbits. Even in the enclosed 'rough lands' beech seedlings exist in abundance, but only where some protective environment occurs does the seedling achieve maturity. The mortality must be enormous.

The seedlings of *Pinus sylvestris* offer a complete contrast. Extensive plantations of this tree exist all over the upland plateau, the woods frequently surrounding waste common land. The seeds find their way to the open commons and the seedling plants practically all reach maturity, so that in a very short space of time a piece of open common land becomes a Scots pine wood. It is obvious that in this case the resinous excretion of the plant preserves it from the attacks of the hordes of rabbits inhabiting the district.

Seedling oaks are rarely seen in any quantity, however prolific the autumn crop of acorns may have been. The oak in this district is principally a tree of the lowland, and in the autumn the droves of pigs from the numerous farmsteads effectually clean up the supply of dropped acorns around the enclosures, and very often in the country lanes also.

Noise Associated with Lightning.

THE thunderstorm which burst upon Petersfield on the night of Aug. 29-30 was accompanied by an unusual effect on the electric lighting system in a house on Bell Hill, distant $1\frac{1}{4}$ miles from Stoner Hill, where the same storm was observed by Capt. C. J. P. Cave (NATURE, Sept. 13).

The lightning was first noticed shortly after 9 P.M., and flashed incessantly every ten to thirty seconds, but was not at its nearest to Bell Hill until 1 A.M. to 2 A.M., when, to judge from the interval of $\frac{1}{3}$-$\frac{1}{2}$ second between the flash and the thunder, a storm centre was within 500 feet.

At the time of observation there were no lights burning in the house. Simultaneously with the nearest lightning flashes, an electric light bulb, hanging from the ceiling, emitted a bluish green light, which flickered and quivered in correspondence with the lightning. This was accompanied by a click in a small pear switch of the lamp in question. Thunder followed the click, after an interval. Other bulbs in the same circuit appear to have been unaffected, which may perhaps be due to the better insulation of their switches. It was next found that the current had failed, and we afterwards learnt that the supply throughout the whole of Petersfield was interrupted at approximately 12.50 A.M. owing to a surge on the high tension line.

It is suggested that a current of electricity, induced in the mains, jumped the switch and illuminated the lamp.

A Cypriote Threshing Sledge.

IN your notice of Mr. Hornell's description of the Cypriote 'dukani' or 'tribulum' in the Research Items in NATURE of Aug. 23, it is stated that "In some parts of Spain and the Canary Islands it is in use without the flints as the straw is required whole". A specimen that I saw at work near Burgos was well provided with flints, which like those in Cyprus are of Miocene age. It is known as a 'trillo'.

Recent Hydro-Electric Developments in Northern Italy.

By Dr. BRYSSON CUNNINGHAM.

IN a preceding article (Sept. 6, p. 371), attention was directed to an essential difference in principle governing systems of hydro-electric development in the Alps and in the Apennines, distinguished in general terms as stations of high and of low altitude. Although my tour in Italy was confined to the northern provinces, and an opportunity was not forthcoming for inspecting developments actually among the Apennines, yet the installations visited within the Alpine region did, as a matter of fact, present certain characteristics of low altitude stations; that is to say, they were in some cases more dependent for supplies of water on rainfall and river flow than on the melting of ice and snow in glaciers.

The first installation inspected was that which constitutes the main source of energy of the Società per l'Utilizzazione delle Forze Idrauliche del Veneto, itself a branch of the great Società Adriatica di Elettricità, which is one of the largest in Italy and among the most important in Europe. It supplies current to a region of considerable extent, covering the whole of north-eastern Italy comprised in the provinces of the three Venetias and Emilia, and stretching from the shores of Lake Garda to the confines of Yugoslavia. The undertaking derives its principal water supplies jointly from the River Piave and Lake Santa Croce, and develops power in a series of five stages from summit level at Lake Santa Croce to the outfalls at Castelletto and Caneva, where the discharge from these stations finally passes into the River Meschio, which conveys it to the sea. The power generated is transmitted at tensions of 70 to 120 kilovolts to the towns and cities of the districts served.

Lake Santa Croce, with its surface area of 8 square kilometres and its content of 120 million cubic metres of water, is one of the most capacious natural storage reservoirs in Italy. Together with one or two smaller sheets of water among the lower slopes of the Venetian Alps some 40 miles or so to the north of Venice, it lies adjacent to the upper basin of the River Piave, and there are indications that at some remote epoch it constituted part of the course of the river in its passage from the Carnic Alps to the Adriatic. The formation of a moraine across the head of the lake has apparently resulted in blocking the passage, and the waters of the Piave are now diverted in a south-westerly direction from a point in the river some five miles above the town of Belluno. Since this diversion took place, instead of feeding the lake as in times past, the Piave has been receiving the overflow from the latter in periods of flood.

Advantage has been taken of these circumstances to effect a joint service. At or about the point of diversion above alluded to, the level of which is some 1280 feet above sea-level, the bed of the Piave has been intersected by an earthwork embankment and masonry dam, to be seen in Fig. 1, with a combined length of rather more than half a mile. The dam provides an overflow crest for a length of about 300 yards, with a set of automatic adjustable weirs for relief in times of heavy flood. The water intercepted by the dam and weir is diverted into a canal on the eastern side of the river, which, partly in tunnel and partly in the open, conveys it a distance of six miles to the northern extremity of Lake Santa Croce, there to augment the natural drainage into the lake and to raise the surface to a level which, when the works in hand are completed, will be 1266 feet above sea-level and will permit, by a lowering of the level to 1180 feet, of the utilisation of a supply of 120 million cubic metres of water for power purposes. To this end, a long earthen embankment with clay hearting is in process of formation at the northern end of the lake.

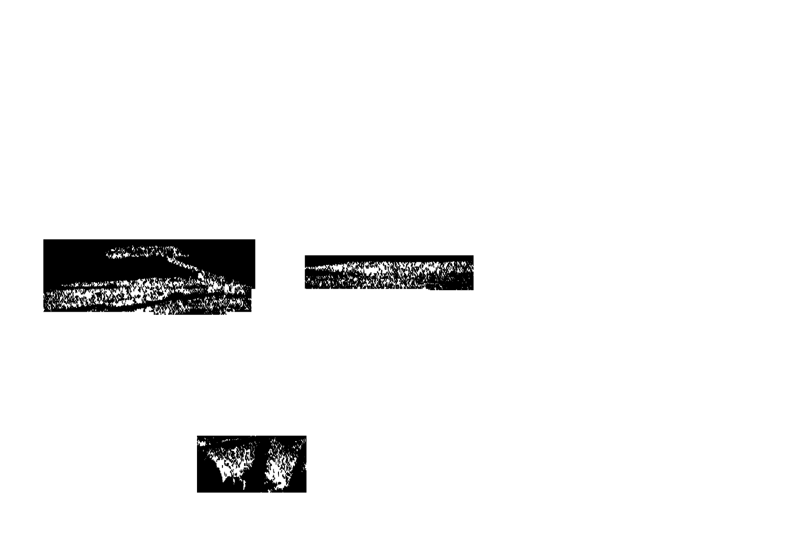

FIG. 1.—Piave and Santa Croce hydro-electric installation; dam and intake at the Piave. By courtesy of the Società per l'Utilizzazione delle Forze Idrauliche del Veneto.

At the south end of the lake, the water passes into a tunnel which has a connexion with the lake at the level of 1059 feet above sea-level. The tunnel is nearly 1¾ miles in length and it transmits the supply to the five pressure tubes, 8 ft. 6 in. in diameter, which enter the power house at Fadalto, where five groups of turbo-alternators, each with a capacity of 24,500 horse power, are installed. There are also two other pressure tubes belonging to an earlier installation, serving two groups of generators of 4000 horse power each. A view of

the power houses and pressure tubes is given in Fig. 2. In its complete development the new power station at Fadalto will possess a sixth unit of 24,500 horse power, making a total of 155,000 horse power generation under a maximum head of 348 feet.

The water discharged from the tail race at Fadalto passes into another natural lake of much smaller size—Lago Morto, or Dead Lake—which is utilised as a storage reservoir for the next stage of descent. The Dead Lake can provide 3 million cubic metres of water in the course of lowering its surface by 13 feet from 905 feet to 892 feet above sea-level. Leaving Lago Morto by a tunnel which is 2 miles in length, the water passes onwards to the power station at Nove, where there are four pressure tubes, 8 ft. 6 in. in diameter, connected up with three groups of generators of 22,000 horse power each and two groups of 8000 horse power each, making a total capacity of 82,000 horse power for the station under a working head of 321 feet.

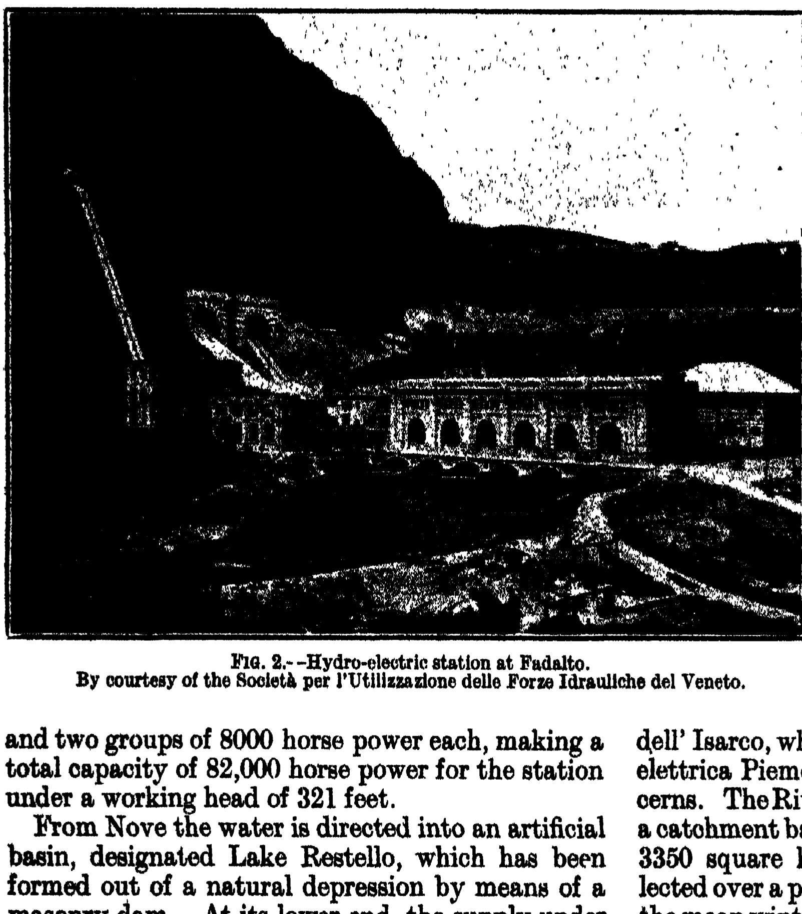

FIG. 2.—Hydro-electric station at Fadalto.
By courtesy of the Società per l'Utilizzazione delle Forze Idrauliche del Veneto.

From Nove the water is directed into an artificial basin, designated Lake Restello, which has been formed out of a natural depression by means of a masonry dam. At its lower end, the supply under a head of 46 ft. reaches the station of San Floriano, where there is a small installation generating some 5000 horse power.

Leaving San Floriano, the water, after passing through the little lake of Negrisiola, enters a long canal which, partly in the open and partly in tunnel, conveys it a distance of 5 miles to Castelletto and 9 miles to Caneva, the two terminal stations of the development, from each of which the discharge passes into the River Meschio, where, as a final duty, it serves to irrigate a district containing 36 million hectares. The stations at Castelletto and Caneva develop 5000 and 60,000 horse power respectively. Thus it will be seen that the series of stations from Fadalto to Caneva serve at the present time to produce no less than 280,000 horse power, and with the extensions in view the total will shortly exceed 300,000 horse power.

The whole undertaking, comprising some 25 miles of waterway in canal, tunnel, river, and lake, with dams, shafts, buildings, and machinery, is a remarkable example of resourcefulness and technical skill in overcoming natural obstacles and constructional difficulties, such as beset in a rugged country the realisation of schemes for turning the forces of Nature to useful ends. The benefit to Italy of such undertakings is of the highest importance: every water horse power realised is the equivalent of about 6 tons of coal per annum, and the Piave-Santa Croce installation alone is capable of rendering unnecessary the annual importation of more than a million and a half tons of coal.

The supply of water being to a certain extent seasonal, there is inevitably a falling-off in production during certain winter months, and, accordingly, the Società Adriatica di Elettricità has to fall back on a thermic generating station as an auxiliary for such periods as the hydraulic supply is insufficient. This station is installed at the new industrial port of Marghera, Venice, and in its present form is capable of producing 86,000 horse power, with provision for future expansion as the need for additional current production manifests itself.

The second station visited was even more northerly than Santa Croce; it is right in the heart of the Dolomites, but here again the local conditions have conduced to the utilisation of a water supply derived from reasonably continuous river flow. The station belongs to the Società Idroelettrica dell' Isarco, which is linked up with the Società Idroelettrica Piemonte, one of the leading Italian concerns. The River Isarco, a tributary of the Adige, has a catchment basin above the town of Bolzano of some 3350 square kilometres. Hydrographic data collected over a period of about twenty years show that the mean winter flow (Nov. 1 to Mar. 31) ranges from 30 to 60 cubic metres per second; that the mean summer flow (April to November) ranges from 72 to 90 cubic metres per second, and that the average for the year lies between 56·8 cubic metres and 72·6 cubic metres. As the mean annual flow only occasionally (3 years in 19) falls below 60 cubic metres, it has been considered permissible to estimate that in conjunction with a working head of 163·50 metres at Cardano, where the generating station is located, a volume of electric energy amounting to 586 million kwh. is capable of realisation, and this over a period of 7400 hours per annum reduces in round figures to 500 million kwh., of which 210 million kwh. are continuous.

The river is bridled by means of a massive dam or embankment, ten miles north-east of Cardano and a little more from Bolzano, containing a set of three large sluices and a smaller sluice. The main sluices have openings 15 metres wide, the small sluice an opening 4 metres wide. Through the intake at the embankment, the water of the Isarco enters an accumulation and sedimentation basin with a serviceable capacity of 290,000 cubic metres, excavated in fairly level ground on the right bank of the river and provided with discharge outlets into the river capable of emptying it completely.

In the station itself are installed five generating groups of 45,000 horse power each and three groups of 14,700 horse power each, making an aggregate of about 270,000 horse power. The maximum demand, or peak load, will absorb the full capacity of four principal groups, leaving the fifth in reserve for the present. The whole of the energy, except the 25 million kwh. generated by the smaller units, which will be supplied to the State railway for the electrified line from Bolzano to Brennero, will be transmitted at a tension of 240,000 volts to the transformer station of Cislago, near Milan, and thence distributed throughout the provinces of Lombardy and Piedmont.

The exceptionally great power of the installation and the unusually high tension of the transmission lines make the Cardano station of the Società Idroelettrica dell' Isarco one of the most notable stations in Europe. It is also remarkable as being the first plant in Europe working at so high a tension. This outstanding enterprise was brought into commission during 1929, but at the time of my visit to the station, at the end of May last, there was still enough finishing work to be done to occupy several months.

The last station in my itinerary in Italy was the new Ponale installation in connexion with the utilisation of the waters of Lake Ledro, which lies rather less than 4 miles north-west of the head of Lake Garda, near Riva. The Ponale is the natural discharge of the overflow from the first lake into the second and there is a fall of 1800 feet between the two. Advantage had been taken of this fact by the municipality of Riva to construct a plant adjacent to the outfall at Ponale so early as 1894. The plant was of small calibre and with gradual accretions only reached 2000 horse power in 1915. The capabilities of the location were obviously very much greater and after the War considerable attention was given to the matter, the problem being whether to enlarge the existing station or to design an entirely new installation on lines of greater convenience and service.

Lake Ledro has an area of 2·1 square kilometres, with a catchment basin of 105 square kilometres. Its surface level is 654 metres above sea level, and it is fed by two subaqueous influents and two torrential streams. Its greatest depth is 48 metres and it has a content of 75 millions of cubic metres of water. It is obviously of glacial origin, and is blocked at the eastern end by a frontal moraine. It acts, therefore, as a suitable seasonal reservoir.

The matter was settled by the action of the combined municipality of Rovereto and Riva, which with expert advice decided upon an installation with a power station at Riva, and the works were commenced in November 1924. Discarding the old power station, a new conduit for the water has been formed by means of a tunnel 6 kilometres in length and 2·9 metres in diameter, running from a point near Mezzolago to an outlet near Riva, where the water enters two pressure tubes of 1·15 metres diameter for transmission to the power house at the edge of Lake Garda below. A view of the power house and pressure tubes is given in Fig. 3.

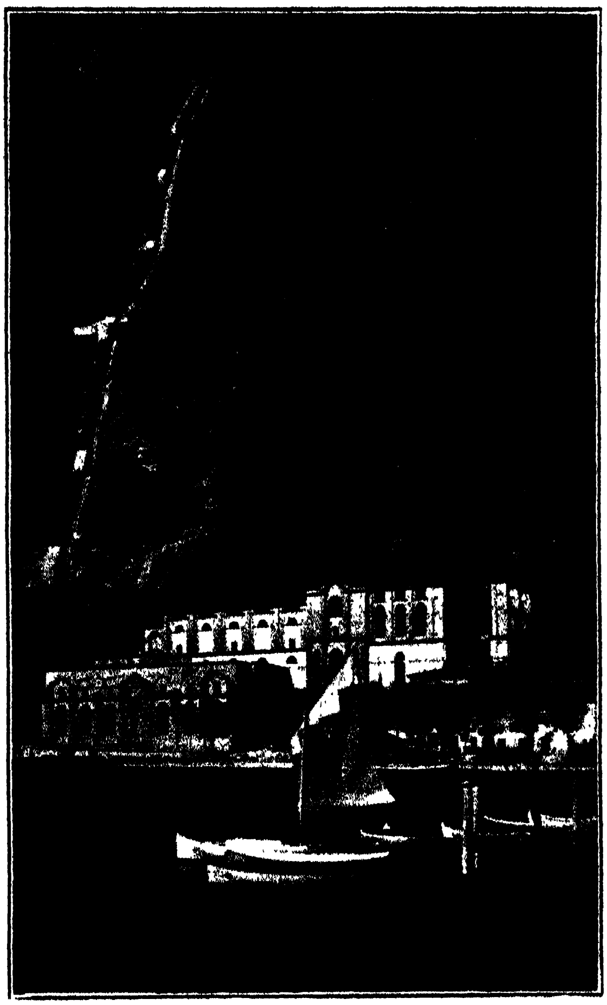

Fig. 3.—Hydro-electric station of the Ponale Installation at Riva, Lake Garda. By courtesy of the Consorzio Industriale delle Città di Rovereto e Riva.

The power generating plant consists at present of two sets of Pelton water wheels, each with an output of 30,000 horse power, coupled to alternators of 21,000 kva. capacity. A third wheel of 45,000 horse power coupled with an alternator of 35,700 kva. is in course of installation and nearing completion. There is provision for a fourth unit.

The foregoing descriptions of plant and installations, which, despite their individual importance, form but a small portion of the activities of the Italian nation in regard to hydro-electric generation, will enable some idea to be formed of the projects which are now in hand and are playing so important a part in the industrial and commercial development of the country.

Present-Day Problems in Taxonomic and Economic Botany.*

By Dr. A. W. Hill, C.M.G., F.R.S.

Taxonomic workers have tended to fall into one of two categories, for to some a 'species' has covered a wide range of forms grouped around a mean type, while others have taken a more restricted view and their species have represented far smaller and more sharply defined classificatory units. Both methods have been of value; the broader view has had its advantage very often in relation to questions of geographical distribution, while the narrower one has caused us to inquire into questions relating to the origin of species themselves and the significance of so-called 'varieties'. They have also had their drawbacks, since in one case many matters relating to the influence of habitat, general conditions, etc., have not been fully appreciated, while in the other the possibilities of hybridisation, segregation, and adaptation have usually received little or no recognition.

The intensive study of the flora of a region, or of particular genera, such, for example, as *Rubus*, *Taraxacum*, or *Hieracium*, has led in some cases, I feel, to the adoption of a very narrow outlook, which has tended to detract from the importance of taxonomic work in the eyes of the younger botanists. In the past, no attempt was made to study effects of light and shade or other environmental conditions, or to make cultural experiments to test the validity or otherwise of the find. Such experiments may involve controlled cultivation, genetical research, and very careful tabulation of statistics before full light can be shed on the true nature of what may have been regarded as a large 'compound-species' or a host of small, closely allied 'micro-species'.

Until I had the opportunity of visiting New Zealand I was not very greatly exercised about the problems underlying the species question, and was content, like others, to describe a new species from a single specimen. The extraordinary prevalence of hybridisation, however, in the New Zealand flora, seen under the able guidance of Dr. Leonard Cockayne, quickly made me realise how rash it would be to think of describing any New Zealand plant as belonging to a new species with only a single specimen before one. Here, then, is a large and vital problem which, to my mind, very greatly widens the interest and importance of our herbarium studies, since problems relating to the possible hybrid origin of the plants we are dealing with demand careful study in the field, with visits to the countries where the plants are native.

A somewhat parallel case, though of a different order, is afforded by the common mistletoe, *Viscum album*. Tubeuf gives an account of the races of *Viscum album* which are definitely associated with particular host plants. Three definite physiological races, however, are clearly marked: (1) the form which is found on deciduous trees, (2) that associated with the silver fir, *Abies pectinata* and other species of *Abies*, and (3) the form parasitic on *Pinus sylvestris*, *P. Laricio*, and *P. montana*. The races are so far distinct that seeds of the 'pine form', for example, will not grow on the apple or fir, and vice versa. Physiologically, therefore, they are distinct, though morphologically they cannot be separated. A case like this suggests that we may be witnessing the advent of three species from one, and that eventually morphological differences may also become evident.

The vegetation of South Africa supplies some taxonomic physiological problems of a like nature, which up to the present have not been satisfactorily solved. These relate to the difficulty of differentiating between two or more forms of the same species which, though distinct physiologically, cannot be separated on any structural characters. Several such physiological strains are now known in South African species of *Pentzia* and *Salsola*. There are two strains of *Salsola glabrescens*, which grow side by side. One of these plants, with purplish-red young twigs, is closely grazed, while the other, in which the young twigs always appear to be pale-coloured, remains untouched by cattle or sheep until there is nothing else to eat. It would be of great interest, therefore, could we discover how the animals are able to distinguish the palatable from the unpalatable form, since we might then become as acute as they appear to be in appreciating the significance of fine distinctions.

Then again, there are puzzling problems connected with the character of certain species on different types of soil in South Africa: for a species may be a useful pasture plant on, say, a red loamy soil, yet when the same species, growing on tufaceous limestone, is eaten by stock, a heavy mortality may result.

It is also very remarkable that the Indian lac insect (*Coccus lacca*) has directed our attention to the existence of two physiological forms of *Schleichera trijuga* (Sapindaceæ), and to two forms of *Butea frondosa* (Leguminosæ), upon one of which it feeds while the other it does not touch; yet the botanist is unable to separate them in either case!

As it is so desirable that the importance and value of taxonomic work in its widest sense should be better appreciated in our schools and universities, I think it is worth while to say something as to what is now implied by taxonomy in the light of modern developments, in the hope that taxonomy, combined with ecology, may again occupy a prominent place in the studies of our developing botanists.

It is true, of course, that the taxonomist must know his plants and must be able, with careful training, to use to the full his powers of observation and deduction, so that he can appreciate small differences, weigh evidence, and draw up descriptions in comparison with allied species, etc.; but he will not go very far if he stops there.

* From the presidential address to Section K (Botany) of the British Association, delivered at Bristol on Sept. 4.

That we are appreciating now the problems surrounding every species which we are able to examine critically, through studying it in the field, and if need be under cultivation, is a healthy sign; for it is, I think, clear that the taxonomist, in undertaking experimental and field studies, will be able to throw much light on the 'origin of species', and on the meaning and importance of the so-called 'variations' which such experimental study reveals.

This seeking after truth by means of experiment is not exactly a new development, though it may be claimed that the conception and planning, during the past few years, of new lines of inquiry has raised the status of these experiments to the definite plane of research. Isolated experiments to test the persistence of individual forms, varieties, or species have been made since Linnæus's day, but it is only in recent years that they have been carried out under careful control.

The classical experiments of Gaston Bonnier are well known. Daniel and F. Krasan have also published papers recording the direct influence of the environment on plant characters, but it is when we come to the work of Turesson in Sweden and Clements and Hall in America that the importance of transplant work to taxonomists, geneticists, and ecologists can be fully understood. The value of Turesson's work may be said to be that he has been able to come to conclusions as to the different types of variation shown by the plant he has observed, both growing wild and under cultivation, and has been able to demonstrate that in some cases they are of a heritable nature, while in others they are merely fluctuations.

These new lines of research, which bring together ecology, genetics, and taxonomy, are now being actively pursued at Potterne. Thanks to the kindness and keen interest of Mr. E. M. Marsden-Jones, the experiments are being made by him in his garden at Potterne, near Devizes, in co-operation with Dr. W. B. Turrill. Four large raised beds have been made side by side, and each has been filled with a distinct type of soil—clay, chalky clay, calcareous sand, and non-calcareous sand. On each type of soil twenty-five individuals of each of six species are now being grown, all being of known genetic origin. Climatic conditions are being recorded, and full records of all features connected with the growth and behaviour of all the plants on the different soils are being kept. The species transplanted are *Centaurea nemoralis* Jord., *Silene vulgaris* Garcke, *S. maritima* L., *Anthyllis vulneraria* L., and *Plantago major* L., while during this year *Fragaria vesca* L. has been added. It is interesting to find that the most obvious changes are taking place in *Silene vulgaris*, *S. maritima*, and *Plantago major*.

Centaurea nemoralis does not at present appear to be plastic; *Silene vulgaris* is slowly plastic under certain edaphic conditions; *S. maritima* is decidedly more plastic than its congener; *Anthyllis vulneraria* is not plastic, and is not capable of survival under a wide range of edaphic conditions, and *Plantago major* is exceedingly plastic.

In addition to what the taxonomist is seeking to discover from this intensive study of plants by means of 'transplant experiments', he is also anxious to elucidate the problems associated with certain 'critical' British and European genera, such as *Silene*, *Centaurea*, *Rubus*, *Taraxacum*, and *Hieracium*, in which botanists have described a multiplicity of species.

In the case of *Rubus* also it seems likely that carefully controlled experiments would possibly reveal the fact that habitat or hybridisation, rather than a 'fixed' type, was the *raison d'être* of several 'species'. Whatever research may reveal in these genera, it has been shown in *Centaurea* that at least three described 'species' are of hybrid nature, for exact counterparts of *Centaurea jungens* Gugl., *C. pratensis* Thuill., and *C. Drucei* C. E. Britt. have been artificially produced at Potterne.

An important development, arising out of the more intensive study of wild species and possible hybrids and the associated genetical work and controlled cultivation which is so pregnant of far-reaching results, is the need of greatly extended herbarium records and field notes. For genetical work to be of permanent value it is essential that ample material of the parent plants and their offspring should be preserved for reference; and in the case of assumed wild hybrids, representative specimens of the parents and of all the linking forms are required. I am glad to say that at Kew we have now established special 'herbaria' for genetical specimens and for hybrids, where specimens forming as complete a set as possible are kept together, apart from the general herbarium collection. We have also formed a collection of fruits and seeds, which it is hoped in course of time will be as comprehensive and complete as is the collection of the vegetative and floral specimens in the general herbarium.

Now let me turn to some problems on the economic side. In the first place, I would direct attention to the interesting observations made by Dr. A. B. Stout and others on the flower behaviour of Avocados, *Persea gratissima* Gaert. (Lauraceæ). These afford an excellent example of the assistance that the botanist can render to the grower and of the practical application of a remarkable botanical phenomenon of great scientific interest.

The Avocado pear bears hermaphrodite flowers, but they exhibit a daily rhythmic alternation of sexes reaching maturity for the entire plant. This synchronous dichogamy apparently reaches a perfection of phsyiological regulation to ensure cross-pollination unknown in any other group of plants. All the flowers that may be open at any one time, on trees of the same clonal variety, are in either the female or the male condition. If the trees belong to one of the varieties placed in 'Class A' by Stout, of which the Taylor variety is taken as an example, the flowers when they first open in the morning are found to be functioning as females with a receptive stigma, but the anthers are not yet mature. About midday these female flowers close, for none but flowers in the female state are open on the trees, and another set of flowers then opens in the early afternoon, normally

without any overlapping, so that there are never on any tree of 'Class A' flowers in the male and flowers in the female condition open at one and the same time. These afternoon flowers are found to be in the male condition with the stigma withered; the anthers are in an upright position, with their valves open and shedding their pollen.

Careful investigation of trees of 'Class A' has shown that the flowers, when they first open, function as females for some four hours in the forenoon; they then close about midday, remain closed all night and all the following morning, and reopen on the afternoon of the second day in the male condition. Self-pollination of individual flowers is thus rendered impossible by this sex-alternation, and since there is normally a definite time interval, about midday, when no flowers on trees of the same 'Class' are open, cross-pollination on the same tree or between different trees of the same clonal variety can rarely occur.

This rhythmic phenomenon is all the more remarkable because there is an entire reversal of the process just described in other clonal varieties and individual seedlings, which Stout places in his 'Class B'. In trees belonging to 'Class B' the flowers are in the *male* condition when those of 'Class A' have their stigmas receptive, and are *female* when the pollen of 'Class A' trees is being shed. These reciprocating changes in sex thus provide the opportunity for mutual cross-pollination between the trees of 'Class A' and those of 'Class B'. The practical application of this discovery scarcely needs pointing out, but it is clear that an orchard planted with trees of only one variety is not likely to yield a rich harvest of fruit!

With regard to pistachio nuts, which are grown as a crop in California, the problem facing the plant breeder, if he is to satisfy the grower, is to produce varieties bearing nuts which crack naturally. If varieties are produced the nuts of which have to be cracked by hand, they are of no value commercially, since the labour cost involved in cracking by hand in the United States is prohibitive if the nuts are to be sold at a profit! Fortunately, scientific research has now produced the desired article, and those who delight in pistachio ices, etc., can rest assured that they are coloured and flavoured by the genuine article and not by some synthetic product.

Limes, again, the staple industry of Dominica, present a curious and difficult problem. The wither-tip disease has made it imperative to carry out experiments with the object of producing races or varieties immune to the disease.

There seems good prospect of success attending these efforts. Dominica, however, is very hilly, and the lime bushes are grown on such steep hillsides that hand-picking of the fruit would be well-nigh impossible. The lime of commerce has the useful habit of shedding its fruit when ripe, so that the Dominican peasant merely has to go and collect the fruit under the trees or bushes. The problem before the plant breeder, therefore, is to produce a lime which not only is immune to disease but will also shed its fruit when ripe. Unless this second essential can be attained, the new variety is of little or no commercial value.

Dr. Walter T. Swingle's researches on the pollination of the date palm (*Phœnix dactylifera* L.) are of great interest: "Each species of *Phœnix* seems to have determined its peculiar action in ripening the fruit of the date palm. The amazing thing is that the pollen of the huge Canary Island palm used on the date palm produces a small seed, quite different from the ordinary date seed, and small or medium-sized fruit that ripens late, whereas the tiny palm *P. Roebelinii*, which has the smallest seeds of any *Phœnix*, when used to pollinate the date palm, causes the formation of large seeds, and makes large dates which ripen extremely late." The economic importance and scientific interest of these discoveries need no comment.

Systematic botanists in the past have, I think, been rather too apt to regard the 'species' they have described as fairly definite units, recognising and recording from time to time 'varieties', but, as I have said earlier, frequently without sufficient material to enable them to say what such varieties really represent, or how constant and definite they may be. In some cases they may be the so-called 'Jordanons', while in others, no doubt, as we are beginning more fully to realise, they are the resultants of hybridisation. For the majority of plants the occurrence of such 'varietal' forms appears to be of little more than purely scientific interest, and they may be passed by with only a casual comment.

When, however, almost any plant comes into the limelight of applied botany and is found to be of some economic value, then the importance and significance of varietal differences at once become apparent. A few cases may be cited in illustration:

Para rubber (*Hevea brasiliensis*) is considered to be a good botanical species, but a careful examination of the trees now being grown in plantations in the East reveals a number of forms, very similar as regards their morphological characters, but showing marked physiological differences, especially with regard to the yield of latex.

A similar problem, where the systematic botanist requires the assistance of his economic colleague, has recently been investigated in Australia by Messrs. Penfold and Morrison. This concerns the oil yielded by *Eucalyptus dives* Schæur. *E. dives* is a species easy of botanical determination, and is of economic value for its oil, which has a piperitone content of about 45–50 per cent, which is used for the manufacture of thymol and menthol. Oil has been obtained yielding only 5–15 per cent of piperitone—morphologically, however, the trees were true *E. dives*—while others contain oil with less than 5 per cent piperitone and 45–75 per cent cineol. It might be thought that ecological conditions are concerned in these striking differences—for a typical form and three distinct physiological varieties have been recognised by their oil characters—but the type form with 40–50 per cent piperitone has been found growing alongside the variety B, containing only 10–20 per cent piperitone with 25–50 per cent cineol. Here, then, is an

interesting piece of investigation which brings the botanist into alliance with the chemist. A similar problem exists with regard to camphor, where, as is well known, two, and perhaps more, physiological varieties exist in the species *Cinnamonium Camphora*, which botanists are unable to separate.

Then again, the tung oil trees, *Aleurites Fordii* and *A. montana*, the seed of which yields a very valuable drying oil, are now being introduced through Kew and the Imperial Institute to all suitable Dominions and Colonies. In these trees the flowers are borne in clusters, and each flower-cluster usually consists of a large number of male flowers surrounding a single female flower. It was noticed that certain trees bore two or three female flowers in each inflorescence. Selected seed from this 'multiple-cluster' type appears to transmit this characteristic, and trees showing this favourable variation may thus be expected to crop more heavily and yield more oil than trees with only one female flower in the cluster.

The problem, therefore, which may arise is analogous to that which confronts us with Para rubber in the matter of latex-yield or with cacao as regards permanent poor-yielders and permanent heavy-yielders. Cases such as these, and there are many others of a like nature, afford an apt illustration that economic and systematic botany can provide romances, possibly of more scientific interest to the botanist than to the commercial planter, but of so great material importance to the latter that the botanist looks to the man of affairs for the financial assistance to help him to discover their solution.

This brief summary will suffice to show that we are living in an era of progress and development, and that we are alive to the opportunities offered of widening our outlook and our interests in the domains of taxonomic and economic botany. As I have hinted earlier, our studies in taxonomic botany, to be living and of practical value, need to be transported from time to time from the herbarium to the field. In this way only can we realise fully the extent and character of variations, the effects of soils and climates, and the prevalence and significance of physiological races.

By the widening of our horizon through travel and by means of vegetational studies in the field, I feel myself on sure ground in maintaining that we are thereby more efficient, more enlightened, and more useful taxonomists, both in the pure and applied directions, than if our studies were strictly confined to the examination of the dried and mounted specimens in a herbarium.

Vast and enthralling as is the prospect, we seem somewhat to have failed to attract a sufficiency of able recruits. If this is so, then we must needs look for the reason. We may and, in fact, I think we are apt to say, like the 'children sitting in the market-place', 'We have piped unto you and ye have not danced'; but with whom does the fault lie? May it not be, as regards taxonomic botany, that we have piped on a wrong note, that we have 'in fact 'mourned' in a minor key, and have failed to pitch our tune on the high note of enterprise and endeavour?

Need I say I refer to the millstone of nomenclature, which encumbers and weighs down the neck of the systematic botanist. The theme itself, 'taxonomic botany' in its widest sense, is full of charm and interest, but it has been so obscured that many have failed to be attracted by the grandeur and harmonies of its melody. Much of our failure to attract disciples is due, I fear, to the misplaced activities of those whom I might call our taxonomic 'Scribes and Pharisees', who have tended to substitute the shadow for the substance. It remains for us to point the way and bring the labourers into the vineyard.

We are hampered to-day in our pursuit of scientific research by the all-important and interdependent problems of recruitment and remuneration. With regard to recruitment—and naturally I am speaking only with regard to botanical science—are we fully satisfied with the efforts, laudable as they are, that are being made in our schools and universities, for training the rising generation in biological science? A good deal has been said recently about the advantages and disadvantages of early specialisation in science in the schools, at the expense of a more 'liberal' education. We realise that the last years at school are the time for laying the foundations of a sound education, and it is certainly a debatable matter whether the now prevalent severe competition (I might almost say scramble) for scholarships at the universities is not, after all, detrimental to the recruitment of those who should develop into the scientific naturalists for home and overseas appointments.

There is no question that the scientific training now given in many of the schools of Great Britain is of a very high order, and that it is given with the most splendid enthusiasm. But nevertheless may we not, owing to competition between school and school, be unduly forcing the pace and producing a superficial scientific precocity in our youth which will not stand the strain?

Science should not be looked upon as a task, but as a guiding tendency, for it is only by regarding it in this way that we can expect to produce the men with a true interest in and enthusiasm for scientific research. The flowering stage, so to speak, has been achieved before the roots and leaves have developed sufficiently to bear the fruit, and our young plants, raised from seed which may have fallen on stony places, will be found prematurely to wither away.

Then again there is a danger of the groundings of science being neglected at the universities, since there is a tendency to assume that the standard of school science teaching is that of the scholarship holder. There are, however, many who turn to science after they have had the good fortune of receiving a classical education, and I could mention botanists who only discovered their natural inclination and aptitude was towards science after they had entered the university.

There is still need to point out that the services which science can render, and for which there is so great a demand, cannot be obtained without making due provision for the cost.

News and Views.

Hearty congratulations are extended to Prof. W. Mitchinson Hicks, who celebrated his eightieth birthday on Tuesday last, Sept. 23. Born at Launceston, he was educated at a private school in Devonport, proceeding thence to St. John's College, Cambridge, being placed seventh wrangler in 1873. Prof. Hicks was principal of and professor of physics in the University of Sheffield from 1883 until 1905. At the Ipswich meeting of the British Association in 1895 he was president of Section A (Mathematics and Physics). The Royal Society awarded him a Royal medal in 1912, during the presidency of Sir Archibald Geikie, for his researches in mathematical physics, and especially for his investigations on the theory of spectroscopy. Among researches specially associated with his name may be mentioned those on hydrodynamics, and particularly on vortex motion, published in the *Philosophical Transactions*. Prof. Hicks was elected a fellow of the Royal Society in 1885, and has served on the council on several occasions.

Friday next, Oct. 3, will be the hundredth anniversary of the birth of Albert Günther, one of the most distinguished naturalists in England in the second half of last century and for twenty years keeper of the Department of Zoology in the British Museum. To mark the centenary, his son, Dr. R. T. Gunther, of Oxford, has prepared a bibliography of his father's writings, which has been published as a supplementary number of the *Annals and Magazine of Natural History* (August). A brief biographical sketch is prefixed, followed by a tabular analysis showing the wide zoological and geographical range of the subjects dealt with. Apart from the personal interest, the list of books and papers will be of great use to zoological bibliographers, since it catalogues not only the works well known to all students of the groups dealt with, but also numerous short notes in such periodicals as the *Field* which are sometimes difficult to trace. The first paper on the list is an article on animal poisons, published in 1853. The last item is the "Appendix to the History of the Collections in the Natural History Departments of the British Museum", issued in 1912, giving the general history of the Department of Zoology from 1856, the year before Günther entered the Museum, to 1895, when he retired on reaching the age limit. His death on Feb. 1, 1914, spared him the sorrow of witnessing the conflict between his native land and that of his adoption. It is to be hoped that Dr. R. T. Gunther may find occasion to expand his sketch of the life of one to whom more than to any other single individual is due the present position of the zoological departments of the British Museum.

A joint discussion on the relation between past pluvial and glacial periods was held between the Sections of Geology, Geography, and Anthropology at the recent Bristol meeting of the British Association, with Prof. H. J. Fleure in the chair. Prof. J. W. Gregory, who was probably the first observer to correlate equatorial pluvial with European glacial periods, devoted his remarks in the discussion to the emphasising of difficulties in taking correlations beyond the broadest outlines. Misses Gardner and Caton Thompson from work in the Fayum, Mr. Leakey from work in Kenya, and Mr. Armstrong from work in Rhodesia, all stated that they had been led to the conclusion that there were in the Pleistocene two pluvial maxima separated by a period of relative aridity. Dr. Sandford (from Egypt) had not been able to find evidence of a mid-Pleistocene arid period. European workers indicated that there was a tendency to look upon the Mindel ice age as a major phenomenon and upon the Riss and Würm phases as episodes of a second major glaciation. Prof. Sölch (Heidelberg) said that he thought Central European opinion was trending towards the idea of the subdivision of the Pleistocene ice age mentioned above, and urged British workers to bear in mind that orographical changes (an uplift of perhaps 500 metres) were among the phenomena of the later Pleistocene ice age. He gave as the general opinion of Central European glaciologists the view that the Hotting breccia belonged to the Mindel-Riss interglacial period. Dr. C. E. P. Brooks gave Dr. G. C. Simpson's view of the succession of conditions in the ice age, and then stated some of his reasons for not accepting the idea of a long arctic interglacial in the middle of the ice age. He showed that a weakening of the monsoon, and consequent aridity, would be the inevitable result of heavy glaciation on the Central Asiatic Highlands. Prof. Barbour showed that in China in the Pleistocene a pluvial period separated two more or less arid periods characterised by loess. Mr. L. A. Cammiade's observations in South India agreed with those of Prof. Barbour in China.

The National Radio Exhibition which was held at Olympia on Sept. 19-27 was nearly twice as large as that held last year. The radio industry is apparently one of the few industries which are practically unaffected by the world trade depression. There are no unemployed on the register of skilled workmen in the radio trades and they are steadily absorbing unskilled labour. Since Madame Melba broadcast from Chelmsford about ten years ago, the progress made in perfecting the transmitting and receiving sets has been extraordinarily rapid. This is due to the fact that from the start it was recognised that progress could only be made when based on scientific principles deduced from careful physical researches. The tendency towards a standardisation of types was very apparent in this exhibition. The prices varied from about £30 for a good 'all-electric' set down to about 30*s*. for a serviceable radio set. In the making of 'all-electric' sets the manufacturers have proceeded on very similar lines of development. Good Continental reception necessitates a four-valve set, arranged preferably with a small outdoor aerial. Ability to receive at least twenty stations can be guaranteed. The lowering of the royalty charged for valves has led to the use of a greater number of them. The European stations have wave frequencies varying between 155 and 1400 kilocycles per second, and the

'all-electric' sets as a rule can be adjusted so as to receive any within this range. But few of them can be adjusted for the short-wave emissions, varying from 3748 (Rome, Prato Smeraldo) to 18,821 (Java, Bandoeng). This is no real drawback to dwellers in Europe. The British Broadcasting Corporation has put forward a scheme for an Empire broadcasting service. This will be discussed at the forthcoming Imperial Conference. It will be of interest to learn whether any of the Dominions wishes to join in this scheme.

The summer meeting of the Newcomen Society took place at Liverpool on Sept. 15–17, thus enabling members to visit the exhibition in St. George's Hall, and the exhibition and pageant in Wavertree Playground in connexion with the centenary celebrations of the Liverpool and Manchester Railway. One day, however, was devoted to visits to certain small factories at Prescot where tools are still made by hand, and to Rainhill, the site of the famous locomotive trials of 1829. Though marine chronometers are made by various London firms, much of the mechanism is made in a small workshop in Prescot by two workmen who have inherited a business a hundred years old and possess the requisite skill and experience. In other shops were seen hand file cutting, hand broach making, and the manufacture by hand of high-class pliers and wirecutters. In file making, the steel blank in the soft state is held down on a lead block by two straps pulled down tight by the foot of the file cutter. The tools necessary are the chisel and hammer, both of special shape so as to render the action of the cutter natural. Skill is easily and quickly acquired and the teeth on a file seven or eight inches long can be cut in less than ten minutes. It is the burr raised by one cut which forms the guide to the tool for the next cut and enables the work to be done so quickly and accurately. In broach making similar dexterity was shown. The broaches being made varied in size from fine needles to lead pencils, but all were tapered and five-sided. The broach was held in a pair of pliers and laid in a groove in a bone block while being filed, and the accuracy with which the pliers were turned a fifth of a circle at each stroke of the file was not the least surprising part of the work. In the making of pliers and cutters, there were operations of an equally interesting character, and it was not a little remarkable to find these hand industries still able to hold their own in the days of mass production.

On Sunday, Sept. 21, M. Laurent-Eynac, the French Minister for Air, unveiled a statue to Clement Ader, one of the pioneers of flight, at Muret in the Haute Garonne. Ader's experiments were carried out in the nineties of last century. Through the writings of Mouillard he studied the flight of birds in Algeria, and in 1890 built an aeroplane of bat-like form and fitted with a steam engine, which on Oct. 9, 1890, is said to have flown a distance of 150 feet. He then built a larger machine on the same lines, to which he gave the name the 'Avion', which was tried in the presence of the French military authorities, but without success, in October 1897. Ader's experiments in France, it will be seen, were contemporary with those of Lilienthal in Germany, of Pilcher and Maxim in England, and of Chanute and Langley in the United States.

The relics of Andrée's expedition of 1897 which were found last August on White Island (or Giles Land) by a Norwegian expedition have arrived in Norway on their way to Sweden. The *Times* has published a preliminary report of the Swedish experts who have examined the remains and diaries. There were three men in the balloon when it left Danes Island, Spitsbergen : S. A. Andrée, N. Strindberg, and K. Frankel. The bodies and diaries of all have been found. The balloon came down on the ice on July 14, 1897, three days after leaving and the day after the last message was sent by carrier pigeon. This was in about lat. 83° N., long. 30° E. Instead of striking south for Spitsbergen, the men appear to have sledged eastward. They got into eddies in the drifting pack-ice and had great difficulty in making progress. By Aug. 10 they were in lat. 81° 55′ N., long. 29° E. At times the drift was even north-west. Eventually they were carried on the only part of White Island where a landing is possible, the greater part being ice-covered. There they landed on the south-west early in October 1897. Andrée's notes continue until the end of September, and Strindberg's until Oct. 17. A number of instruments, photographs, and scientific observations have also been found.

In the twenty-fifth report of the Committee on Photographs of Geological Interest, presented at Bristol to Section C of the British Association, 141 new photographs are recorded, bringing the total of the collection to 8287. From the well-known Reader series of negatives 39 are contributed to the present additions. The Isle of Wight landslip of 1928 is illustrated by photographs by Mr. J. F. Jackson. Prof. S. H. Reynolds contributes sets from Torquay, Snowdon, South London, and Portraine. The submerged forest of Swansea Bay and the raised beach of Hope's Nose, Torquay, are illustrated by Dr. A. E. Trueman and Mr. L. N. Wheaton. River action in South Wales is portrayed by a set from Dr. T. F. Sibly, and Mr. W. F. Chubb has presented a fine view of the Severn Bore. Lundy Island is the subject of a series by Mr. A. O. Rowden. Copies of individual photographs can generally be obtained directly from the photographer concerned, to whom application should be made for further particulars. Addresses are given in the report. The Committee has already published three sets of geological photographs, and these have been widely used in teaching throughout the world. It will therefore be of very special interest to geologists to know that two new sets of 25 photographs each are expected to be available by the end of the present year. For information concerning these new issues application should be made to the honorary secretary of the Committee, Prof. S. H. Reynolds, The University, Bristol.

Progress in the application of scientific methods in the production of raw cotton is well exemplified in the recent issue of the *Empire Cotton Growing Review*

(vol. 8, No. 3), in which questions of breeding, ginning technique and cotton quality, and blackarm disease come under discussion. The chief interest, however, is focused in a résumé of the progress of the cotton industry under successive German and British rule in Tanganyika Territory. Under German administration, experience proved the vital importance of planting on suitable soil and of growing the right kind of cotton, owing to the ravages of diseases and pests on such types as Egyptian and Ceravonica. Lighter soils give better results than the heavier ones, and production is greatly assisted by proper rotation of crops. Under British rule the output has increased rapidly. Production by plantation labour is uneconomic under ordinary conditions, and the policy now is that of definitely encouraging the native smallholder. Under this régime, native production has risen from forty-three per cent in 1922 to from sixty-three to seventy-four per cent of the whole in the succeeding years. It is estimated that during the last nine years more than one million sterling has passed into the hands of the cotton-growing native of the country. Cotton production is much influenced adversely by various factors, of which several may operate at once. Local demand for food crops or other agricultural products, inadequate transport, and unfavourable climatic conditions are but a few of the problems which demand attention, and the solution of which means so much to the economic well-being of the mandated territory.

As a converter of electric energy into heat the electric fire has an efficiency of one hundred per cent. It is desirable to know how much of the energy is converted into radiant heat and how this heat is distributed. In the *Journal of the Institution of Electrical Engineers* for September, Prof. Parker Smith gives the results of experiments on ordinary electric fires which were made to determine their radiant efficiency. This nearly always lies between 55 and 70 per cent, the rest of the heat being carried away by convection. He made tests on five modern types of gas fire and found that the radiant efficiency was from 40 to 50 per cent, the bulk of the remaining heat escaping as flue heat and the rest being carried away by convection air currents. In a room heated by an electric fire, the temperature for comfort of the air should not be less than about 55° F., hence the fire itself needs to produce air convection currents in addition to those produced by objects in the room receiving direct radiant heat. The principal difficulty in connexion with electric heating is the question of ventilation. Means must be provided for admitting fresh air, while the warmed air should escape near the ceiling. Ceiling-panel heating is sometimes employed, but in this case the convection heating is less than with floor and wall panels. If the temperature of the heating elements is raised by over-running, the heat carried away by the convection currents increases more rapidly than the radiation heating. It would seem that ordinary electric fires run at approximately the right temperature, but more attention should be paid to designing proper ventilation for the rooms in which they are placed.

FOR some years the advisability of having an extended high tension system of electric supply has been considered in Northern Ireland and Mr. J. M. Kennedy has been asked to report on the scheme. In the *Electrician* for Sept. 5 a résumé is given of his report and of a supplementary one issued on Aug. 29. The scheme links up the principal centres of population in Londonderry, Tyrone, and Fermanagh with the generating station of the Londonderry corporation. It would also link up with networks projected at Dungannon and in Antrim. The western area has been divided into eight districts and it is proposed to connect them by 33,000-volt lines. The report shows that considerable economies can be effected in this way. The capital cost would be about a million pounds, which is about one-fifth that of the Shannon scheme. Several Irish engineers are agitating that before the final decision of the Northern Government be taken, the possibility of effecting still greater economies by having an all-Ireland electricity programme be considered. We think that it would be for the mutual benefit of the north and the south to have an all-Irish grid. As the power available at the Shannon power station is limited and nothing has yet been done in constructing the northern grid, the time seems opportune for discussing the larger scheme. In a few years' time the water power of the Liffey will probably be harnessed and the falls on the Erne in the north-west of Ireland could be utilised. The water power from the Erne would be particularly helpful to both governments. Mr. Kennedy mentions in his report that it would be a comparatively simple matter to connect the northern system with the Free State grid at Newry. The *Irish Electrician* points out that it would be to the mutual advantage of Dublin and Belfast. An agreement between the two governments would be necessary.

So far back as 1880 Sir William Siemens made experiments on the effect of illuminating plants by electric light. He found that with a few hours' illumination he could make tulip buds blossom, and he suggested that in the future gardeners might become independent of sunlight and regulate the growth of the plants entirely as they wished. In 1920 Jacobsen, a Norwegian engineer, observed that the position of the electric power cables underground could be told at once by the strips of green grass above them. These two fundamental observations form the basis of the procedure in electro-horticulture, which is being carried out in the Experimentalfaltet—a little 'science town' near Stockholm. In the *Electrical Times* for Sept. 4, Charlotte Gast gives an account of the satisfactory results already obtained by Sven Oden and Gustaf Lind. The work is mainly to expose different kinds of plants to light coming from incandescent lamps. As in November 1929 Stockholm had only 23 hours of sunshine, the results were sharply defined. The plants subjected to the electric light were much the more flourishing. Conclusions have not yet been obtained as to the best length of time for the exposure. Cucumbers, which ordinarily require five weeks to produce marketable fruit, can be ripened in three weeks with the use for a few hours

daily of artificial light. The experiments made on the heating of the soil by electric cables have given promising results. It has been proved definitely that it does pay to heat the soil in greenhouses for the cultivation of melons and cucumbers. Nine hundred Swedish gardeners and florists are using soil-heating equipment. A usual price in Sweden for a night electric load for gardening is a farthing a unit. If this could be supplied at a cheaper rate, as in Norway, where there is a special commercial night-rate of a tenth of a penny per unit, Swedish growers could force early spring vegetables and compete successfully with market gardeners situated much farther south.

THE partial absorption of X-ray quanta observed photographically by Dr. B. B. Ray, which was the subject of two letters in NATURE of Sept. 13, p. 398, is one of the large group of atomic phenomena which involve quantised transfers of energy. All have three partially distinct aspects--the magnitude of the energy interchange, the probability that it shall occur, and the relation between the initial and final directions of motion of the reacting particles. There is good evidence from Dr. Ray's measurements, as well as from others made with an ionisation chamber by Prof. Bergen Davis and his collaborators, that the energy change in this case is a decrease, or, more rarely, an increase, in the energy of the X-ray quantum, by an amount determined by the X-ray spectra of the atom traversed. In a further letter which we have received from Dr. Ray, which we are unable to find space to print in full, he has pointed out that certain experiments which might be held to disprove the existence of this effect have been performed under conditions which he would expect to yield only a feeble modified radiation. The chief ground for this statement is the important one that the modified quantum is believed by him to proceed almost, if not exactly, in the original direction of the unmodified quantum, a hypothesis which, he shows, fits in very reasonably with the observations. No estimate appears to have been made as yet of the probability of transfer of energy in this way, but it is evidently not unduly small, and sufficient data probably exist to permit of a rough calculation. Should the reality of this effect continue to be admitted, as seems likely, it will undoubtedly open up a convenient method for investigating certain types of soft X-rays indirectly, much as the Raman effect is now applied to the study of the infra-red spectrum.

ALTHOUGH it has been said that there are already too many scientific periodicals in existence, we have no hesitation in offering a cordial welcome to *Oceania*, a new publication which is devoted to the study of the native peoples of Australia, New Guinea, and the islands of the Pacific. It is issued on behalf of the Australian National Research Council under the editorship of Prof. A. Radcliffe-Brown as the organ of the Anthropological Research Fund, which was established three years ago by a grant from the Rockefeller Foundation and an amount equal to the grant contributed by Australia. It is not intended that *Oceania* should be a mere record of observation. Its policy will be based on the view that the study of the culture of a people can be carried out only by specially trained scientific workers in the field, whose object is not only to record facts, but also to discover their interpretation, that is, their meaning and function. Thus, in the first issue, Miss Camilla H. Wedgwood on war in Melanesia, Prof. A. Radcliffe-Brown on social organisation in Australian tribes, Dr. Raymond Firth on a dart contest in Tikopia, and Miss Ursula McConnel on the Wik-Munkan tribe of Cape York Peninsula, each dwells on the functional aspect, in the respective societies, of the facts which they record and analyse. Beside the four papers mentioned, *Oceania* includes in its contents reports of the proceedings of societies, notes and news, and reviews of books dealing with the area covered by the Anthropological Research Fund. As a record of the researches now being undertaken by Australia, largely owing to the initiative and organising ability of Prof. Radcliffe-Brown, *Oceania* will be of enduring value to students of social anthropology.

IN the recently issued year-book for 1929 of the Carnegie Institution of Washington, Dr. Sylvanus G. Morley publishes his usual annual review of the activities of the Institution in excavation among the Maya ruins of Central America. The excavations at Chichen Itzá and Uaxactun continue to constitute the major operations, but this year a medical survey of the modern Maya living in the neighbourhood of these ancient cities was instituted. This survey already shows promise of producing much information of value to the anthropologist. The chief interest of Dr. Morley's report this year, however, does not lie in the account of the excavations and their result. At the close of the report he makes the pregnant suggestion that the time has now come for excavation in Central America to be more highly organised. He points out that there are now four major expeditions regularly in the field: those of the Carnegie Institution, the British Museum, the Field Museum, and that of the Government of Mexico, which is carrying out investigations in the northern Maya area and the southern part of the republic. In addition, universities, museums, and individuals are engaged on the work of excavation and exploration from time to time. He therefore suggests that a committee should be formed composed of representatives of the bodies interested and engaging in this work. The duties of the committee would be to survey the present state of knowledge, to formulate the problems suggested as the result of this survey, and then, in order to avoid overlapping and waste of effort, to allocate the investigation of these problems to the institutions willing and best fitted to take up the work.

A RÉSUMÉ is given in the *Bell Laboratories Record* for August of the scientific experiments which were carried out by that corporation's acoustical research department for the Noise Abatement Commission of New York City. Complaints had been made that the average city-dweller is continually submerged in an ocean of sound made up by the horns of motor cars, squeaking brakes, rumbling trucks, roaring subway

trains, the rapid fire of riveting machines, and the noise of radio loud-speakers. To find out which were the worst offenders, about ten thousand outdoor observations were made from a truck of the Health Department by the Bell engineers. It was found that trucks, motor cars, elevated trains, tramways, and other agencies of transportation were the principal offenders. Next came the noises made during building operations, often of greater intensity but much less widespread in their effects. It is hoped that the measurements made will enable the special committees which have been appointed to reduce the noise evil. It is stated that this appreciably decreases the vitality and efficiency of the citizens of New York. The figures obtained during the survey are of interest. The most intense noises were furnished by building operations. In one case a riveter produced a noise level of 99 above audibility, the arbitrary unit chosen being in decibels. The use of explosives in the subway excavations of the Bronx produced a noise of 98 decibels. The ever-present roar of street traffic, however, was found to vary between 50 and 80 decibels. A subway express passing a local station produces a level of 96 decibels, a steamship whistle slightly less, and elevated trains a level of 90 decibels.

THE Annual Report for 1929–30 of the executive committee of the Central Library for Students marks the close of the Library under the management which has controlled it since its foundation fourteen years ago. A new constitution has been adopted, the Library has become the National Central Library, and future reports will be issued by the new committee. The purpose of the Library is generally to supply, to serious readers, books which they are unable to obtain for themselves or at their local libraries, and that means as a rule the more expensive books, or books dealing with highly specialised subjects, for which there could be no local demand. Unfortunately, the committee points out, lack of funds prevents the purchase of those very books, and borrowing libraries have been protesting that they cannot obtain the books specially wanted. Unfortunately also the unrestricted grant of £5000 a year recommended by the Public Libraries Committee has been reduced by His Majesty's Treasury to a grant of £3000 allocated for three specific purposes, which do not include the purchase of books. During the year the volumes in the Library have increased from 45,177 to 59,606, of which 3506 have been purchased and 10,923 have been presented. Of the utility of the Library there can be no doubt, but the committee is far from satisfied with the service it has been able to give to meet the most pressing needs of readers.

WE have received vol. 2 of the Collected Papers of the Rowett Research Institute, edited by the director, Dr. J. B. Orr. The first volume was published in 1925; the present covers the ensuing five years and includes the majority of the papers published during this period by the workers at the Institute, but excluding those published by members of the staff working in other parts of the Empire. The volume contains seventy-one papers and runs to 588 pages. Broadly speaking, all deal with the subject of animal nutrition, including the food supply and also certain diseases; a few are concerned with the subject of human nutrition. In a prefatory note Dr. Orr mentions that the Duthie Experimental Stock Farm should be completely established during the present year; that the Imperial Bureau of Animal Nutrition has been established in connexion with the Reid Library to serve as a clearing-house for information on nutrition; and that a residence for temporary workers and visitors is to be built in the vicinity of the Institute. The co-operation of the Institute in work in different parts of the Empire is in increasing demand, and is an indication of the growing value of the research work carried out by the members of the staff and their collaborators.

UNDER arrangements made at the beginning of this year, the Sociological Society was united with the newer organisation of Le Play House, to form an Institute of Sociology, pure and applied. The Institute will continue and extend the work for which both the Society and the House have become well known, namely, study and research in sociology and the development of civic and regional surveys. During the present year a number of preliminary and experimental surveys have been conducted at home (for example, Chichester) and abroad, and detailed civic surveys at Chester and Brynmawr have been directed or assisted. Le Play House was founded by Mr. and Mrs. Victor Branford. Both the founders have since died, and their property has been left in trust to further the objects of the Institute and forms the nucleus of an endowment which, it is hoped, will be added to from other sources. The annual conference will be held in the Duveen Gallery at the Imperial Institute on Saturday and Sunday, Nov. 1 and 2. The sessions will take the form of lectures and discussions on sociological and survey topics. The annual exhibition will be open, in the same gallery, on Oct. 20–Nov. 3 inclusive, and will include representative examples of survey materials from various parts of Great Britain.

WE much regret to announce the death, which occurred on Sept. 18, at the age of seventy-eight years, of Prof. H. B. Dixon, C.B.E., F.R.S., honorary professor of chemistry in the University of Manchester.

THE inaugural sessional address of the School of Pharmacy of the Pharmaceutical Society of Great Britain will be delivered this year on Oct. 1, by Dr. Arthur W. Hill, Director of the Royal Botanic Gardens, Kew. The Pereira Medal of the Society will be presented also on this occasion.

A SMALL brochure has been issued by The British Drug Houses, Ltd., London, N.1, describing in handy form the medical products issued by this firm. A brief description of each substance is followed by notes of the indications for its use, of its methods of administration and modes of issue. Among the newer products mentioned, we noted carotene, which has been shown to act as a potent source of vitamin A in animal experiments; digitalis leaf tablets, physiologically standardised to contain a definite fraction of an inter-

national unit; and sodium morrhuate, which is now being used for the injection treatment of varicose veins. A therapeutic index of diseases is also included. We have also received from the same firm a leaflet describing the applications and uses of the acriflavine group of antiseptics; illustrative cases are quoted and a selected bibliography is appended. These antiseptics have a wide use in the treatment of wounds and a great variety of septic conditions.

"METHODS and Problems of Medical Education", 17th Series, has been issued by the Rockefeller Foundation, N.Y. This volume deals with departments and institutes of anatomy, histology, and embryology in all parts of the world, including Lima, Batavia, and Manila. It is profusely illustrated with plans and views, and gives details of the accommodation, staffing, courses of instruction and research work, and budgets of a number of the leading schools of the world.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An organising secretary of the Land Utilisation Survey of Britain —Dr. L. Dudley Stamp, c/o The London School of Economics, Houghton Street, W.C.2 (Sept. 29). An engineer in the Offices of the Divisional Road Engineers —Establishment Officer, Ministry of Transport, Whitehall Gardens, S.W.1 (Oct. 1). A graduate assistant in electrical engineering at the Wolverhampton and Staffordshire Technical College — Clerk to the Governors, Education Office, North St., Wolverhampton (Oct. 4). A lecturer in experimental psychology at the Otago University, Dunedin—High Commissioner for New Zealand, 415 Strand, W.C.2 (Oct. 10). Assistant executive engineers for the Indian Service of Engineers, and assistant executive engineers for the Indian Railway Service of Engineers —The Secretary, Services and General Department, India Office, Whitehall, S.W.1 (Oct. 31). A teacher in mechanical power plants equipment for evening classes at the Central Polytechnic, Croydon—Education Officer, Education Office, Katharine St., Croydon. A temporary full-time lecturer in mechanical engineering at the Municipal Technical School (The Gamble Institute), St. Helens — Secretary for Education, Education Office, St. Helens. An evening lecturer in geography at the West Ham Municipal College—The Principal, West Ham Municipal College, Romford Road, Stratford, E.15. Assistant engineers for the Public Works Department of the Federated Malay States—The Crown Agents for the Colonies (quoting M/1990), 4 Millbank, S.W.1.

Our Astronomical Column.

Pluto.—The first observation of Pluto after its conjunction with the sun was obtained by Prof. M. Wolf at Konigstuhl on Aug. 29 (on two plates taken with the reflector); the approximate position is R A. 7^h $27{\cdot}9^m$, N. Decl. 21° 54′, which is in accord with the ephemeris in *Lick Bulletin*, No. 427. The period adopted in that *Bulletin* is 249·1661 years. Many other computers have found similar periods, so that the orbit is now known within narrow limits. The *Bulletin* gives approximate ephemerides for every year back to 1890, in the hope that further images may be found. Prof. Wolf has found an image that may be Pluto on a plate exposed on 1914 Jan. 23^d 7^h 33 0^m Konigstuhl M.T.; R.A. (1914·0) 5^h 57^m $54{\cdot}93^s$, N. Decl. (1914·0) 17° 37′ 23·0″; the Lick ephemeris, reduced to the same equinox, gives 5^h 58^m 1^s, 17° 38′. As some approximations were used in preparing the ephemeris for past years, the discordance is not excessive.

Prof. T. Banachiewicz gives a full description in *Cracow Circ.* No. 26 (see also *U.A.I. Circ.* No. 296) of the work carried out at Cracow on the orbit of Pluto. It will be remembered that the ephemerides calculated there led to the detection of an image of Pluto on an Uccle plate of Jan. 27, 1927; that in turn led to the detection of the images of 1919 (Mt. Wilson) and 1921 and 1927 (Yerkes). Individual observations of Pluto in 1930 give residuals that occasionally attain 3″. These residuals explain the very erroneous orbits that were first published. Prof. Banachiewicz shows that by using a large number of observations made in 1930 an orbit can be deduced that is similar to those that were obtained with the aid of the observations made in 1919, etc.

The following additional observations have been received from Prof. Wolf: they are for 1930·0.

1930 Aug. 30^d	2^h	$36{\cdot}5^m$ U.T.	R.A.	7^h	27^m	$57{\cdot}97^s$	N. Decl.	21°	53′	55·9″
Sept. 5	2	35·0		7	28	26·88		21	53	16 7

The star places are from the Abbadia Catalogue.

Orbits of Binary Stars.—*Bull.* No. 195 of the Astronomical Institute of the Netherlands contains several determinations of orbits by G. P. Kuiper. The orbit of the close pair β232 is now determined for the first time. Since its discovery in 1876, 240° of the orbit has been described. The period found is 91·2 years, periastron 1914·9, *a* 0·368″, *e* 0·326. Using Eddington's mass-luminosity curve, the masses are 0·95 and 0·91 of the sun, the absolute magnitudes 4·5 and 4·7, parallax 0·0148″.

OΣ77 is a pair with equal magnitudes in which there is liability of confusing the two components when they emerge from periastron; Jackson and van den Bos adopted different identifications and found periods of 95·2 and 51·6 years respectively. The ten years that have since elapsed decide against the short period. Mr. Kuiper finds the period 122·6 years, periastron 1883·4, *a* 0·472″, *e* 0·170; the hypothetical mass of each star is 1·13 sun, absolute magnitude of each 3·97, parallax 0·0146″.

OΣ82 is in the Hyades, and the brighter star is a spectroscopic binary; Prof. Hussey gave the period of the visual pair as ninety-eight years, using observations up to 1900; subsequent observations show that this is too short, and the new period is 487 years. The parallax appears to be close to 0·02″, and the sum of the three masses is between two and three times that of the sun.

The fourth system studied is a fivefold one. It is shown that the double star Σ1999 is probably in physical connexion with the triple system ξ Scorpii, from which it is distant 281″; the common parallax is estimated as 0·04″; the masses of the components of the triple system are given as 1·50, 1·39, and 0·95 of the sun; those of the binary are stated to be equal to each other, but their values are not given; the two systems are about 7000 astronomical units apart in the direction normal to the line of sight. The shift of the second system relatively to the first is only 0·25″ in sixty-four years, whereas the proper motion of ξ Scorpii in that period is 4·7″.

Research Items.

Growth - Changes in Physical Correlation. — Dr. Joseph Bergson, in *Human Biology*, vol. 1, No. 4, publishes the result of a study of the relation of height, weight, and chest measurement in the human male from birth to maturity in accordance with Pearsonian biometric methods. His object is to show that, as conjectured, the alternate stimulus and retardation known to be exhibited during growth are incidental to an all-pervading interdependence of one structure and another. He finds that intercorrelations between height and weight, weight and chest circumference, and height and chest circumference all show significant variation with age. The correlations between height and weight show in their trend on age alternate maximum and minimum points in the neighbourhood of ages 1·5 years, 3 years, 6 years, 11 years, 14 years, and 21 years. The correlations between weight and chest measurement and height and chest measurement, as well as between height and weight, show a maximum point in the neighbourhood of 14 years. Each of the other statistical functions, means, standard deviations, and coefficients of variation, also shows in its trend with age a maximum point in the neighbourhood of 14 years. This is taken to be associated with adolescence and a subsequent decline is regarded as a "post-pubescent decline". The relative size of the correlation coefficient after about 10 years is highest for weight-chest circumference and smallest for height-chest circumference. Between the ages of about 6 years and 10 years the height-weight correlation coefficient is higher than the weight-chest circumference coefficient, while the latter and height-chest circumference retain the relative position they occupy after 10 years.

Archæology of the Mediterranean Lands.—Excavations continue to furnish further links in the history of the Mediterranean region. A distinguished visitor to Section H (Anthropology) of the British Association at Bristol was Dr. Miloje M. Vassitz, of Belgrade. His excavations on the now famous site at Vinča yielded in 1930 important evidence of commercial relations between Vinča and the south-east, the Ægean, Asia Minor, and Cyprus. Remains of wattle and daub buildings with a floor consisting of horizontal beams overlaid with mud plaster, the surface of which had been fired, were reminiscent of floors discovered at Tcherna-Voda on the Danube in Bulgaria, and also in south-west Russia. Obsidian implements suggest a link between Vinča and the Bükk district, as does one type of decoration on the pottery. The most important find of the year, however, was a type of pottery related to Minyan ware. This would confirm Dr. Vassitz's dating of the beginning of Vinča culture as early Troy II., since Minyan ware belongs to the Middle Minoan and Middle Helladic periods. Details of the work are being published in *Man*. Prof. J. L. Myres read a report from Mr. W. A. Heurtley on a Neolithic and Early Bronze Age site on the south side of the Haliakmon in western Macedonia. Mr. Heurtley's excavations have added an important piece of evidence as to the earliest incursion of northerners into Greece, largely based on pottery finds. A complete skeleton, buried in a crouched position, was found and awaits examination by an anthropologist. Since this skeleton is probably that of one of the invaders, great interest will attach to its characters. Miss M. A. Murray, working in Minorca on the clearance of the temenos round megalithic structures, which consist of an upright stone slab with a horizontal slab placed tablewise on the top, discovered painted Iberian ware of a type associated with eastern Spain and southern France.

A Dart Match in Tikopia.—Dr. Raymond Firth describes in *Oceania*, vol. 1, No. 1, the game of dart throwing as played in Tikopia, an island lying between Banks and Vera Cruz islands in the Pacific. This game was a popular sport in old Polynesia, and records of it, varying in details, are preserved among the Maori, in Samoa, Niué, and Fiji, where it drew the interest of the whole community. In Tikopia, matches are watched with most intense interest by crowds which include women and children. Though primarily a public diversion, it is also closely connected with the social organisation and religious belief of the people. The game is played on a *marae*, a long, narrow platform of ground, about 130 yards long by six to seven yards in width, which is cleared of all vegetation. The *tika* or dart has a head of hard wood about five inches long, which curves gently from base to point and is highly polished to make it glide gently over the ground when the dart is thrown. It fits by a tang into the socket of a reed shaft about three feet long. When thrown with a low trajectory, it flies for about fifty yards and then, on striking the ground, glides along for another seventy or eighty yards. Additional impetus is gained by a protective ring of coconut fibre on the forefinger, which fits into a notch in the base of the shaft. The game is played by two sides of twelve to twenty players each—known, figuratively only, as "the Bachelors" and "the Married Men". Actually the sides are drawn, irrespective of their married status, primarily from two clans. The composition of the sides, rules, order and methods of playing are traditional, dating back to the times when men were gods, and thus as the 'sport of the gods' the game is taboo, especially on certain occasions, as for example, when the object is to seek efficacy for the land. In the scoring, only the dart thrown farthest on either side counts; and a complicated system of scoring points and cancellation of points scored makes a complete victory by one side a rare occurrence.

Adaptations of the Kangaroo Mouse.—In 1891 C. Hart Merriam described "one of the most remarkable of the many new and interesting mammals that have been discovered in North America during the past few years" the kangaroo mouse, *Microdipodops megacephalus*. It is of no economic importance, one way or the other, for it lives largely upon seeds, but its adaptations are well marked, as E. Raymond Hall and Jean M. Linsdale show in the most complete account that has been written of this rare creature (*Jour. of Mammalogy*, vol. 10, p. 298; 1929). The eyes are large and black, and suggest nocturnal habits—the only occasion on which any individual was known to bite was when it was endeavouring to escape from a strong light. Stiff projecting hairs occur on the sides of the hind feet, and the hind feet and lower legs are greatly lengthened—a young mouse repeatedly jumped out of a can without touching its sides, although the sides were seventeen inches high and the can only ten inches in diameter. The auditory bullæ are greatly inflated and reach their maximum relative size in kangaroo mice, yet the ear pinnæ are extremely small, consistent with the burrowing habits of the species. The mice are found only in the Great Basin region at altitudes ranging from 4000 ft. to 6000 ft., but the distribution is far from uniform, because fine sandy soil associated with vegetation appears to offer the only suitable habitat.

Clyde Muds.—An investigation into the Clyde muds with a new sampling apparatus was undertaken by Mr. H. B. Moore ("Muds of the Clyde Sea Area

I, Phosphate and Nitrogen Contents", *Journal of the Marine Biological Association of the United Kingdom*, vol. 16, No. 2, March 1930). The instrument is described in a separate paper in the same number of the *Journal* by Mr. Moore and Mr. R. G. Neill ("An Instrument for Sampling Marine Muds"). A column of mud from 12 in. to 16 in. can be taken, the depth ranging from 10 fm. to 70 fm. The sampler is worked by hand and consists of a heavy brass body containing a glass tube open at both ends when descending. This falls under its own weight and drives deeply into the mud, which partially fills the tube. A valve at the top closes when the sampler stops, and by this, and by its own friction against the glass, the mud is held in the tube while the sampler is hoisted. This has been in use at the Millport Laboratory for some months and is very satisfactory, serving for collecting the mud fauna and for chemical analysis. The phosphate and nitrogen contents of the mud at thirty-three stations in the Clyde Sea area were determined at 5 cm. stages, down to 20 and sometimes 30 cm. below the surface. The phosphomolybdic method was used in estimating the phosphates and the Kjeldahl method for the total nitrogen. Whilst no general relation was found between phosphate or nitrogen values and the depth of water, the phosphate values in depths of less than 40 metres all lie close together and fall off with increasing depth in the mud, usually showing a rise at the 10 to 15 centimetre level, and the nitrogen values usually fall with increasing depth in the mud. Stations with strong tides usually show low phosphate and nitrogen values.

Japanese Sipunculids.- Dr. Hayao Satô in his "Report of the Biological Survey of Mutsu Bay, 15. Sipunculoidea" (*Science Reports of the Tôhoku Imperial University*, Fourth Series (Biology), Sendai, Japan, Vol. 5, No. 1, April 1930) records nine species, four of which are new to science. Critical notes, keys, and good figures are given and there is an extensive bibliography. The new species *Phascolion ikedai* lives in a state of commensalism with the madreporarian coral *Stephanoceris carthausi*. This had already been discovered by Ikeda, who observed them in the Sagami Sea, but although noting that the *Phascolion* was new he did not name it. This is the only species of *Phascolion* hitherto known to live as a commensal with a coral, although several cases are recorded for *Aspidophora*. A polychæte belonging to the genus *Syllis*, more than 40 mm. long and 1 mm. broad, usually lives with the *Phascolion* in the coral.

Fish Breeding in Aquaria.—Goldfish breeding is always popular. In the *Aquarian Review* for July (vol. i. No. 12), the president of the British Aquarists' Association, Dr. H. B. Jones, gives useful instructions and hints to would-be breeders. The eggs should be hatched out quickly with a slightly raised temperature and much attention must be given to the food—infusoria at first, later sifted daphniæ. In the same number Mr. L. B. Katterns begins a series of articles dealing with the breeding of tropical fish, the first giving instructions for equipment and general requirements. Here again temperature is necessarily of great importance, and the author states that it is easier to keep the aquarium heated to an even temperature than to keep a cold-water aquarium cool during hot weather.

Eruption of Komagatake (Japan) in 1929.— Near the south end of Hokkaido, the northern island of Japan, is an inlet, Volcano Bay, opening to the east The volcano, Usu-san, of which there was a great eruption in 1910, lies near the northern shore. On the opposite side is the volcano Komagatake, 3740 feet in height, of which the most violent eruption known occurred in 1640 and the latest on June 17, 1929. This has been closely studied by Mr. H. Tsuya and seven colleagues, and the results are described in a valuable series of papers published in a recent *Bulletin* of the Earthquake Research Institute (vol. 8, pp. 237-319; 1930). The eruption began at 0·30 A.M. with an earthquake and rumbling noises. The activity gradually increased until about 10 A.M., when there was a great explosion, after which it subsided. On June 22–23, a microseismometer, a pair of tiltmeters, and a pair of gravity-variometers were erected in a hut about five miles north of the crater. From June 23 to July 10, 377 earthquakes were recorded, the amplitude being usually less than 1 mm., so that few were sensible to human beings. The foci seem to have been close to the surface. The tilt-curves show several abnormal tilts which were clearly connected with changes in the pressure-gradient and also with pulsations of the ground preceding small outbursts. After the eruption, the levelling was repeated along two lines on the north and west bases of the mountain. This showed that the ground had sunk, the curves of equal depression being parts of ellipses with their centres at the crater. The greatest subsidence measured 2 ft. 9 in. There was no trace of change in the gravitational field large enough to be recorded by the instruments employed.

Nuclear Disintegration of Boron.- In two papers in the *Zeitschrift für Physik* for July 21, W. Bothe and H. Franz have given an account of a fairly complete investigation of the ejection of protons from boron nuclei, under the influence of α-particles from polonium and radium-C′. The protons were registered by one of the new forms of electrical counters which is sensitive to single α-particles and H-particles, but is practically unaffected by β-rays and γ-rays. At least three groups of protons are produced, the fastest two being fairly homogeneous, with maximum ranges of 33 cm. and 74 cm. in air when set free by the polonium α-particles. The energy of the protons decreases as the angle between their direction of motion and that of the incident α-particle increases, although their number does not vary much with direction, whilst a decrease in the energy of the individual α-particles has a greater effect on the number of protons than on their range. A very recent investigation, to which reference is made by Dr. Bothe in a footnote, has also established that a hard γ-radiation is emitted when certain light elements are bombarded with α-particles.

Analysis of Groups of Alpha-Rays.—Sir Ernest Rutherford, Mr. F. A. B. Ward, and Dr. Wynn-Williams have contributed a paper to the September number of the *Proceedings of the Royal Society* on a method for analysing groups of α-rays, in which the ionisation produced by each particle is amplified linearly by valves until it can be measured by a relatively insensitive galvanometer. This form of counter can be used either with a single ionising chamber or with a double differential chamber, the latter type in particular being most useful for the study of complex beams, revealing immediately, for example, the previously unknown short range α-particles emitted in the dual disintegration of radium-C. These new rays are not homogeneous, and consist of two groups, a main one of range 4·1 cm., and a subsidiary one of range 3·9 cm., a result which is in accord with the complexity of the 4·8 cm. particles from thorium-C, which had already been established by magnetic analysis and again verified in the present investigation, and with the complexity of the 5·5 cm. particles from actinium-C. The 8·6 cm. particles from thorium-C′, the 7·0 cm. particles from radium-C′, and the 3·9 cm. particles from

polonium are, however, homogeneous within the limits of the resolving power of the counter, and it thus seems possible that the complex α-ray spectra are associated with radioactive elements of odd atomic number, a prediction which is being tested by an analysis of the rays from protoactinium. Fuller details of the apparatus are to be published subsequently.

Mobility of Ions in Pure Gases.—An investigation of the motion of ions in gas at high pressure, in which the modern technique for the purification of materials for electrical measurements at low pressures has been used, is described by A. M. Tyndall and C. F. Powell in the September number of the *Proceedings of the Royal Society*. The results are very surprising in the remarkable dependence found in the properties of the positive ions on the presence of minute traces of impurities. It has been known for a long time that the mobility of the negative carriers is largely affected by impurity, but it has now been shown that when the amount of the latter has been reduced to the stage when the negative carriers are almost unaffected, the positive ions still do not attain their maximum possible speeds in the field. To ensure that the measured mobility of an ion is the true mobility of a positive ion in its own gas, it is necessary that the residual impurity should be reduced to the order of a few parts in a million, the total pressure being 100 mm. or more, and the opinion is expressed that no significance can be attached to the values of the mobility of the positive ion previously obtained in any gas. These experiments are being elaborated with a system of alternating fields of square wave-form, in place of the sinusoidal wave-form, which is less suited for accurate determination of the mobility, but it has already been established definitely that the true value of the mobility of the positive helium ion in helium is considerably greater than had been supposed, and of the same order as the value deduced from classical kinetic theory.

Impact Resistance of Steel Castings.—The May number of the *Canadian Journal of Research* contains a paper by R. W. Moffat, of the University of Manitoba, on the effect of low temperatures on the resistance of steel castings to impact. This subject is of importance from the known increased frequency of failures of machine parts in severe winters. Many studies of this effect have been carried out by previous workers, but we miss from the references given in the paper any mention of the interesting work of Robin, published as a Carnegie Memoir of the Iron and Steel Institute in 1911, which clearly showed the greater resistance to impact at low temperatures due to the use of nickel as an alloying element. The present series of experiments is concerned with castings, and shows that plain carbon steels may have a resistance to impact at $-31°$ C. of only from one-quarter to one-half of that at ordinary temperatures. By heat treatment this resistance is increased very considerably. The impact value falls off with increasing carbon. Vanadium or nickel or a combination of the two metals increases the resistance to impact. Castings with 2-3 per cent of nickel have about the same resistance at low temperatures as those with 0·18-0·22 per cent of vanadium. Normalising at 870°-900° C., followed by reheating to 620°-700° C. and cooling in still air is recommended.

The Melting Point of Iron.—Amongst the black-body radiators used by Dr. C. H. M. Jenkins and Dr. M. L. V. Gayler in an investigation of the applicability of optical methods of pyrometry to the measurement of metallurgical temperatures (*Proceedings of the Royal Society*, vol. 129, p. 91) was a very simple and ingenious one consisting of a bubble blown in the molten metal. The bubble was formed on the end of a narrow tube of refractory material, which served in addition as a viewing tube, and was found to behave quite satisfactorily in iron, but not in gold or palladium. The final result given for the melting point of iron of very high purity is 1527° ± 3° C., the local standard of reference being the melting point of palladium, 1555° ± 2° C. The optical pyrometer used was of the disappearing-filament type.

Tri-organo Thallium Compounds.—The only organo-thallium compounds previously known were of the type R_2TlOH, but in the July number of the *Journal of the American Chemical Society*, H. P. A. Groll describes the preparation of thallium triethyl, $Tl(C_2H_5)_3$, from thallium diethyl chloride and lithium ethyl, in absence of oxygen and moisture.

Explosion Rates.—Although several attempts have been made to account for the high speed of propagation of gaseous explosions, the detailed microscopic molecular mechanism of propagation from one layer of gas to the next has not received much attention. In the August number of the *Journal of the American Chemical Society*, B. Lewis has attempted to calculate the velocity of propagation of gaseous explosions on the basis of the theory of reaction chains. A single interaction between two molecules may generate a product which reacts with the next suitable molecule it encounters, the process continuing in like manner from layer to layer by reason of regenerated active products through a large number of steps or a chain of reaction. By means of a special hypothesis as to the division of the energy of reaction among the rather arbitrarily selected numbers of degrees of freedom of the molecules, Lewis finds that the energy on the carrier finally reaches a maximum limit which remains constant, and by equating this to $\frac{1}{2}Mv^2$, where M is the mass of the carrier, the value of v, the velocity, is found. The agreement in several typical cases is good.

High Frequency Steel Furnaces.—The paper on high frequency steel furnaces by D. F. Campbell, which was read on Sept. 16 at the autumn meeting in Czechoslovakia of the Iron and Steel Institute, contains much valuable information. The melting of steel in an ironless induction furnace has long been known as an efficient and economical method of making tool steel. But this is only a very limited application of its uses. At present the largest furnaces in use have a capacity of 20–25 cwt. and have an output of 20 tons per day. For making tool steel, 5-cwt. furnaces melting one charge per hour are commonly used. They are very appreciably cheaper to operate than gas or coal fired crucible furnaces and the necessary labour is less costly and easier to obtain. The quality of the steels produced in this way, especially those containing complex alloys, is much better and more homogeneous. The remelting of low carbon stainless alloys of the chromium series without any 'pick up' of carbon is of value. In small furnaces of extra high frequency (about 20,000) the melting of hard materials of the tungsten-chromium-cobalt-carbide group, which are being cast in form moulds, at a temperature of between 2000° to 2300° C., can be carried out. A comparison is made between a steelworks equipped with six 75-ton open-hearth furnaces, producing 6000 tons a week, and ten 6-ton high frequency units giving the same output and casting direct into ingot moulds. It is shown that the capital cost of the latter equipment is considerably less and that it has many advantages. Improvements in the design of motor-generator sets for producing the high frequency currents have led to an overall efficiency of between 85 and 90 per cent being obtained.

Eleventh International Zoological Congress.

THE Eleventh International Congress of Zoologists, which met in Padua on Sept. 3–11, under the presidency of Prof. Paolo Enriques, attracted more than six hundred members, representing thirty countries. The British delegates were Dr. F. A. Bather and Dr. G. C. Robson (representing H.M. Government), Dr. K. Jordan, Dr. H. W. Parker, Lieut.-Col. J. Stephenson (Indian Government), and Prof. A. Willey. In the Aula Magna of the University, surrounded by memorials of Galileo, Morgagni, Vesalius, Falloppio, Casseri, and Vallisnieri (nor should we here forget Linacre and Harvey), the Congress was formally opened by H. E. Alfredo Rocco, Minister of Grace, Justice, and Culture, as representative of the Government and as president of the Italian Committee for International Intellectual Co-operation. He expressed the deep practical interest felt by the Italian Government in zoological studies, alluded to the contributions of Italians from Leonardo da Vinci to the present day, and mentioned the Zoological Station of Naples and the Biological Institute of Messina as schools open to the students of the whole world.

Prof. Enriques, in an eloquent address, laid particular stress on the Fascist organisation of the Congress: the vast concepts and ideals of zoology, he said, led the mind up to that rarefied atmosphere in which the spirit of Giotto hovered when, under the eyes of Dante, he traced the poem of the Gospel on the walls of the neighbouring chapel; inspired by like ideals, every Italian sought to be worthy of his country's past and to base new works on the ancient traditions; but such a national ideal could not develop without the friendly co-operation of all civilised countries, and in that belief he tendered an affectionate welcome to the zoologists of every tongue. Among those who replied was the veteran Richard Hertwig, who alluded to the story of St. Antony of Padua preaching to the fishes, and to the Paduan studies of Paracelsus and Goethe. "There is much talk", he said, "of a United States of Europe: that does not satisfy zoologists; we wish to see all the States of the world united in the interests of civilisation and of science."

The scientific communications were presented to fifteen sections and to general meetings. Since they numbered more than two hundred and fifty, it is scarcely possible to mention more than a few of those dealing with wider questions. In an opening discourse on "Genetics and Evolution", Prof. Caullery maintained that the mutants made known by geneticists are not really new formations but combinations of pre-existing genotypes; that, though they may exist where they first appear, they would be eliminated by natural selection and would not give rise to new species distinguished by the criterion of interspecific sterility. It is difficult, he said, to regard evolution as due to successive mutations.

"Biogeography and Evolution" was the theme of Prof. G. Colosi, who, in most explanations of the known facts, finds difficulties (as of contradictory physiographic changes) that are obviated by Rosa's theory of hologenesis. This assumes a world-wide extension of the original life-forms, with parallel orthogenesis, so that the same or similar species arose in widely-separate regions; thus land-bridges or sea-connexions are unnecessary. Dealing with the distribution of populations, from insect epidemics to the races of man, Prof. F. Bodenheimer attributed the chief influence to climatic conditions. On the other hand, Dr. Boettger's account of "Artbildung unter dem Einfluss des Menschen", exemplified by the snails *Agriolimax lævis* and *Potamopyrgus crystallinus*, seems to prove nothing more than the distribution of mutants by human agency. His title would have been more applicable to Prof. Ghigi's account of crossings in pheasants and guinea-fowls with the formation of alleged new species, themselves fertile but sterile when crossed; Ghigi finds that sterility and fertility are sex-linked characters, and regards hybridisation as an important factor in evolution.

Birds also were the subject of Prof. O. Riddle's experiments on the relation of metabolism to sex; metabolism is influenced by temperature more in males than in females, and the amount of hæmoglobin is also affected; the sexes and their corresponding metabolic types are both reversible. Other papers on sexual characters were contributed by A. Arcangeli, A. Banta, E. Caroli, J. de Mallasz, and E. Padoa, and on hybrids by F. Cavazza and G. Montalenti, while F. Poche discussed the possibility of a third sex.

Returning to problems of evolution, one notes Prof. Enriques' studies in Radiolaria because they show similar minute characters repeated through generically differing forms, much as the varieties of wheat are paralleled in rye. Dr. Robson's researches on the origin and descent of Octopoda lead him to attribute much to orthogenesis. In connexion with Cephalopods, the important paper on their nervous system by E. Seroni should be mentioned. Prof. A. Sewertzoff announced an evolutionary principle as "the substitution of functions", which means the replacement of an organ by a totally different organ that performs a function which is analogous or biologically equivalent to that of the suppressed organ. In the reduction of organs, Sewertzoff claims that those parts disappear first which are the last to be formed embryologically.

Other papers with a general bearing might be cited did space permit, but the practical side of zoology demands mention, since a whole section was devoted to silkworm culture. The address by Prof. Pigorini, director of the Bacological Station at Padua, did indeed deal with important embryological questions. Among the papers here were two by Prof. Matsumura on the silkworms of Japan. A visit to the Station proved of exceptional interest, and the preparations of larvæ by Dr. Amelia Tonon were much admired. Here also may be recalled the R. Stazione di Polticultura near Rovigo, where experiments are conducted on numerous breeds of gallinaceous and other birds.

This last was visited during an excursion which included an inspection of Count Arrigoni's ornithological collection with welcome refreshment at his villa, Cà Oddo, and a banquet at Rovigo, where the Minister of Agriculture spoke. Another excursion was to the Royal Villa at Strà, where the company of four hundred was entertained by Count Giusti, Mayor of Padua, to such effect that "grave and reverend signiors" were seen to join in the subsequent fox-trots. On Sunday there was a delightful trip to Venice and the islands of its lagoon. A ball in the fine rooms of the Casino Pedrocchi and a final dinner offered by the local committee in the great and ancient Sala della Ragione were among other general entertainments. Special invitations were extended by certain ladies of Padua to all ladies attending the Congress.

Some of the general meetings were held in a new Aula of Pathological Anatomy, formally opened by Prof. Cagnetti, while sections met in the various aulæ of the new university buildings. In the Zoological Institute a room was provided for exhibits by members, and hard by was an exhibition of books and apparatus. Here Koristka of Milan showed a new

"Stand A" for monocular microscopes and "Stand U" capable of taking various forms of binocular with either single or double objectives; Reichert of Vienna exhibited microscopes, microtomes, projection and photographic apparatus; Zeiss of Jena had a particularly interesting show of projection apparatus; A. C. Zambelli of Turin showed thermostats for embryological research and microscope observation *in vivo*. Allusion may here be made to the cinema film of young orang-utans shown by Prof. G. Brandes of Dresden, and the remarkable results displayed by Prof. Storch of Graz in his cinema studies of small crustacea under the microscope. In the Library of the University, Profs. Ageno and Ducceschi had arranged an exhibit of old books relating to biological science; an excellent illustrated catalogue was provided.

At the concluding session of the Congress reports were presented from the Commissions on Parasitology and on Nomenclature. It was decided that in future the Congress should be held at intervals of five years. In view of the large number of such meetings, the decision is probably wise, but it is to be hoped that care will be taken not to clash with other congresses in allied sciences. The International Institute of Intellectual Co-operation might be asked to act as a co-ordinating body. These congresses would be more useful if papers dealing with relatively special and trivial points were eliminated, especially when the results have already been published. Attention should be concentrated on general problems, towards the discussion of which authorities in various branches might contribute; and on such forms of co-operation as biological surveys, studies of migration, and especially action requiring government assistance. At present the Commission on Nomenclature seems to be the body that continually does really practical international work, however restricted its field may be. What the Permanent Committee of the Congress does between whiles, not even its members seem to know.

The preceding remarks are not intended to reflect in any way on the organisation of the Padua Congress, for which high praise is due to the energy of Prof. Enriques and the labours of the general secretary, Dr. Fausta Bertolini, with her lively and courteous staff of students of both sexes. Padua preserves the intimate and homely character of an ancient university city, and all its inhabitants united in so warm a welcome that the chief characteristic of the Congress now past was its friendly and homely character; and that, after all, is the chief value of these international gatherings.

The Liverpool and Manchester Railway Centenary Celebrations.

THE Centenary Celebrations of the opening of the Liverpool and Manchester Railway were opened on Sept. 13 in St. George's Hall, Liverpool, by the American Ambassador, General Dawes, and were brought to a conclusion on Sept. 20 by a final performance of the great Pageant of Transport which had been shown night by night in Wavertree Playground.

Enacted on a stage 300 feet long and by some 3500 performers, the Pageant of Transport was designed to show the various methods of transport by animals, sledges, carts, wagons and coaches, and by the early railways. The final scene recalled the events of Sept. 15, 1830, when the Duke of Wellington, Sir Robert Peel, Mr. Huskisson, and other notable persons set out in the first of a procession of eight trains from Liverpool to Manchester. A replica of the original train had been constructed, and it was drawn by a replica of the engine *Northumbrian* which in 1830 was driven by George Stephenson himself. In the Wavertree Playground - a large open space kept solely for games - was also an exhibition of old and modern locomotives, together with examples of up-to-date carriages and wagons. It need scarcely be said that a copy of the *Rocket* was to be seen, while the *Lion*, an engine built for the Liverpool and Manchester Railway in 1838, but now the property of the Liverpool Engineering Society, was under steam and worked "a train of 1830" carrying passengers around a circular track.

While the pageant and exhibition and the shows at Wavertree provided for the popular taste, an exhibition of historic material, models, etc., in St. George's Hall provided food for the student and specialist and fascination for boys and girls. The celebrations have been held under the auspices of the corporations of Liverpool and Manchester and with the support of the London, Midland and Scottish Railway. The responsibilty for the exhibition in St. George's Hall lay with a committee of which Mr. Robert Gladstone was chairman, and its success was largely due to his energy and foresight. While there were scores of model locomotives and a splendid model railway to be seen, the chief features of interest consisted of a series of exhibits illustrating the work of the pioneers, Cugnot, Trevithick, Murray, Blenkinsop, Hedley, Hackworth, Stephenson, and others, and another series relating particularly to the history of the Liverpool and Manchester Railway, much of the material for which came from the Liverpool Public Library.

There was much to recall the famous locomotive trials at Rainhill in 1829, between the *Rocket*, *Sans Pareil*, *Novelty*, and *Perseverance*, and one of the original cylinders of the *Novelty*, recently procured from an old works near Rainhill Station, was on view. The fellow cylinder for many years has been in the Science Museum. Of especial interest to serious students of railway history was the exhibition of a recently discovered letter from Robert Daglish referring to locomotive engines he made in 1812 and 1816. Hitherto nothing has been known of these Lancashire engines, and inquiries at the colliery at which they worked have already brought some interesting facts to light.

A Handbook and Programme of the Centenary Celebrations was available, as were also a catalogue of the exhibition and a bibliography of the printed and illustrated material on the Liverpool and Manchester Railway in the Liverpool Reference Library. The London, Midland and Scottish Railway issued "One Hundred Years of Railways", written by Mr. Dendy Marshall; while Prof. G. S. Veitch's book, "The Struggle for the Liverpool and Manchester Railway", was published just before the celebrations.

Of other events connected with the celebrations mention may be made of the commemoration service in the Cathedral, the unveiling of a memorial tablet on the first railway station in Manchester, the performance of a pageant of the industries of Liverpool by the workers of the railway, and the public lectures in Picton Hall arranged by the Liverpool Corporation. At least two additions will be made to the nation's historic machines as a result of the celebration, as the cylinder of the *Novelty* is to be placed on permanent exhibition in Rainhill Station, and the locomotive *Lion* is to be placed on a pedestal in Lime Street Station, Liverpool.

Sinanthropus.

AT a joint meeting of the Sections of Geology and Anthropology of the British Association at Bristol, Prof. G. B. Barbour, of the Department of Geology, Yenching University, gave a very interesting lecture on "The Geological Background of Peking Man (*Sinanthropus*)." Chou-kou-tien, where *Sinanthropus* was discovered in an abandoned limestone quarry, overlooking the re-entrant margin of the Yellow River delta plain, lies 37 miles south-west of Peiping (Peking), on a branch of the Peking-Hankow railway. The fossiliferous deposit was first reported by J. Gunnar Andersson in 1921, and in the following year Otto Zdansky discovered mammalian material, reporting in 1926 that it contained hominid teeth. In 1928 B. Bohlin, C. C. Young, and W. C. Pei found an adult right ramus, with three molars *in situ*, together with part of another jaw and many skull fragments. In 1929 W. C. Pei, a young geologist on the staff of Yenching University, discovered first fragments of a skull, since reconstructed, and later an uncrushed adult skull. This latter discovery occurred at 4 P.M. on Dec. 2, the last day on which it was possible to work because of the increasingly wintry weather. The skull was embedded in a travertine matrix, and Prof. Barbour described the infinite care and skill with which Dr. Davidson Black removed the matrix, taking repeated casts and photographs, in an effort to ensure that the fullest records should be available for future workers.

The skull is that of a young adult, for the sutures are deep and unfused. The lower face is apparently missing, but the ear-hole and the back of the skull are present; the jaw sockets are massive, suggesting marked biting capacity. Dr. Davidson Black considers that the length of the skull approximates to that of *Pithecanthropus*, which it also resembles in its massive brow-ridges, but the distinct frontal swelling and the development of slight parietal bosses mark it off from the Java skull. A feature of importance in the site is that remains of at least ten individuals have been found, and, curiously enough, all skeletal parts so far recognised belong to the head.

In addition to the richness of the *Sinanthropus* finds, the quantity and variety of the vertebrate remains form a striking feature at Chou-kou-tien.

More than fifty types of mammals, besides frogs, snakes, turtles, and birds, have been recorded. In the three seasons, 1927 to 1929, about 8800 cubic metres have been excavated, and 1475 boxes of fossil material have been removed. The most characteristic types are *Sinanthropus*, *Euryceros* (flat-antlered deer), *Rhinoceros*, cf. *sinensis*, and *Hyæna sinensis*. *Trogontherium* (big beaver) and *Bubalus* (primitive buffalo) also occur. The fauna has suggestions of a southern affinity and is distinctly older than the Loess fauna of Middle Pleistocene date, which includes *Rhinoceros tichorinus*, *Hyæna crocuta*, and *Cervus elephas* in place of those mentioned above. It can be closely dated as very early Pleistocene in view of the absence of truly archaic types and the presence of modern types, including *Equus*, but it is definitely older than the Middle Pleistocene. The fossil material is found *in situ* at various level deposits, and is of essentially the same age from top to bottom.

The finds were made in deposits of breccia, gravel, sand, and clay filling fissures and caves in Ordovician limestone. With the aid of a series of remarkably clear photographs, sections, and block diagrams, Prof. Barbour demonstrated the origin, by dissection, of the various clefts or caves, which at one time must have formed shelters for animals and are now filled with the brecciated clayish or sandy fossiliferous formations, comprising the typical Chou-kou-tien deposits. The interest of the lecture was greatly enhanced by the exhibition of casts of *Sinanthropus* and of a tooth. Prof. Barbour concluded by pointing out that all new data are issued from the laboratory of Cenozoic Research, under the combined control of the Geological Survey of China and the Peking Union Medical College. He paid a tribute to the way in which work has been continuously carried on in spite of the grave difficulties due to the prolonged political crisis in China. Reference was made to the important paper by P. Teilhard de Chardin and C. C. Young in *Bull. Geol. Soc. China* (vol. 8, No. 3, 1929), which not only gives a clear and detailed account of the geological history of the Chou-kou-tien formations, but also has a bibliography of all publications on the subject up to December 1929. Vol. 9, No. 1, 1930, gives further data.

It had originally been planned that Prof. Elliot Smith should open a discussion on the characters and affinities of Peking man, but he decided in early August to go to China to study *Sinanthropus* on the spot. His report, and a further one from Dr. Davidson Black, will be awaited with keen interest.

Staining Yeasts with Methylene Blue.

WORKERS who use the time-honoured method of staining yeasts with methylene blue are familiar with the untrustworthy results often obtained when an attempt is made to distinguish living from dead yeasts. It is now realised that apparently contradictory results may be due to differences in working conditions employed by various workers, and in this connexion a recent letter in NATURE (Brooks, **125**, p. 599; April 19, 1930) may be cited, in which the importance of pH value, concentration and purity of the stain, and of the effects of light are indicated.

Fuchs also (*Woch. Brau.*, **46**, p. 437; 1929: **47**, pp. 171, 183; 1930) has pointed out that the concentration of methylene blue, which is usually 0·0001 per cent, may be increased to 0·001 per cent without any immediate marked change in the proportion of stained to unstained cells. After 15 minutes, however, this proportion may increase very rapidly. If this result is correlated with the fact that granulated cells, which are usually considered dead, stain well, we have a certain amount of evidence that methylene blue is toxic to yeasts after a short period of contact.

Haehn and Glaubitz (*ibid.*, 315) actually showed, however, that preparations from which unstained yeasts were entirely absent grew in wort, and they therefore concluded that cells which take a weak stain are living, though impaired in vitality. The weak staining in the first instance may probably be attributed to adsorption by mucilage on the cell-walls. In both cases a 0·0001 per cent solution is favoured, and Fuchs adds this until the colour is blue-green and immediately counts the deeply stained dead cells. In the case of suspensions in wort the proportion of stain must be increased, as some is adsorbed by the wort-colloids.

Against this increase in stained cells on prolonged

contact must be set the decolorising effect of reductase, which persists when the cell is dead and is greatly increased at low pH values (for example, in wort). The influence of pH values has been accounted for by Fink and Weinfurtner (*ibid.*, **47**, pp. 89, 110, 124; 1930) by the fact that methylene blue is a base, the hydrochloride of which is soluble in neutral or in acid solutions. In alkaline solutions, however, the less soluble base is liberated and is available for adsorption. Thus, at pH 2·2 less than 1 per cent of the cells examined were properly stained, the remainder being pale-blue in colour, whilst at pH 4 a deeper shade of blue was obtained, increasing progressively in depth of colour until, at pH 8, all the cells were deep blue. The marked time-effect is illustrated by the increase in one case of from 5 per cent to 20 per cent of stained cells in 3 minutes (pH 2·6 to 6·8).

Yet another source of anomalous results was traced to the electrolyte-content of the medium in which the yeast is suspended. Thus, staining occurs more rapidly in distilled water than in tap-water, but a trace of electrolyte (for example, salt) added to the former before the addition of the stain inhibits its action. It is not clear to what extent this is due to a corresponding change in pH value, since some substances, for example, dextrose and lævulose, have the effect of predisposing the yeast to staining. Maltose and glycerol are less effective in this respect, while mannitol is inactive. Electrolytes containing chlorides, iodides, thiocyanates, bromides, sulphates, nitrates, tartrates, citrates, and acetates act as inhibitors in decreasing order of efficiency, and it is suggested that their absence renders the yeast-walls more permeable to the stain.

Another important fact which emerges from these investigations is that one set of conditions cannot be formulated for all strains of yeast, so that there appears to be every reason why a study should be made of possible substitutes for methylene blue. In this connexion attention may be directed to the proposal of a 0·25 per cent solution of erythrosin by Devereux and Tanner (*Jour. Bact.*, **14**, p. 217; 1927), and to the use by Tolstouhov of eosin-yellow for pH values above 3, and acid fuschin for pH 0·8-3·0.

International Eugenics Conference.

THE International Federation of Eugenic Organisations held a conference at the Larmer Tree Grounds, Tollard-Royal, Wiltshire, on Sept. 10-15. Eighteen countries maintain membership in the Federation, and many of them sent representatives. Among those present were Sir Bernard Mallet, of Great Britain; Dr. A. Ploetz and Prof. Rüdin, of Germany; Prof. Reichel, of Vienna; Dr. Heuyer, of Paris; Dr. Van Herverden, of Utrecht; Dr. J. A. Mjøen, of Oslo, and Dr. H. H. Laughlin, from the Eugenics Record Office, U.S.A. Mrs. C. B. S. Hodson acted as organiser and interpreter of the conference. One object of the conference was to co-ordinate research in different countries. Reports were received on eugenics and war, and on recent eugenic developments in various countries. Committees were formed or continued for the study of human heredity, race crossing, racial psychiatry, and the standardisation of anthropometrical measurements, physical and mental. Different conferences were held on the standardisation of human measurements, on race crossing, on racial psychiatry, and on human heredity. Miss Tildesley outlined proposals on behalf of English anthropologists for standardising measurements, and Miss B. Schieffelin discussed methods of measuring psychic differences.

In her report on the work of the American Eugenic Research Association on Mental Measurement, Miss Schieffelin pointed out that the search for any such thing as a measurement of hereditary mental endowment has proved a failure. A central clearing-house should be established so that all mental tests could be thoroughly classified and their value gauged. This clearing-house, which would of necessity be an expensive business, would be able to review the situation and plan future research. Workers would be able to apply to it for advice and should be able to obtain the existing position in relation to mental testing and its application to hereditary factors.

Prof. Rüdin outlined a scheme of research on racial psychiatry, and Prof. C. G. Seligman contributed some observations on Chinese and Japanese psychiatry. An afternoon was devoted to papers on human heredity.

A public meeting held in the Tythe Barn, Hinton St. Mary, at the invitation of Capt. Pitt-Rivers, on "The Urgency of Eugenic Reform", was attended by many local people. Sir Arthur Keith spoke on eugenics from the evolutionary point of view; Prof. Ruggles Gates, on human heredity and segregation in racial crossing; Prof. Rüdin, on heredity of insanity; and Dr. C. J. Bond, on dangers of racial decay and the remedy.

Sir Arthur Keith, in his address, briefly traced the development of modern man from the time of *Pithecanthropus erectus* through the age of agriculture and showed how gradually the production of race was sacrificed for the accumulation of wealth. The new age, the eugenic age, is, it is hoped, to be one of constant race improvement. There are many difficulties in the way of execution of eugenics ideals, chief of which are human prejudice, emotion, and passion. The Church is falling into line, placing its blessing on attempts at racial improvement and paving the way for the more practical side which is the work of the eugenist. The evolution of man is not, as some people imagine, at a standstill, for it is slowly but surely progressing, and must be directed by the knowledge of the eugenist.

Dr. C. J. Bond emphasised the presence of a considerable element of mental and physical degeneracy in the general population. He pointed out that the remedy lay in first of all carrying out an exact ascertainment of the degree of mental and physical deterioration in the various social groups and then applying the principles of sterilisation and segregation. This would in course of time eliminate the defective and unstable members of society.

At another public meeting, cinema films showing various features of cell division and embryonic development were shown by Prof. Ruggles Gates, and Prof. Elton Mayo, of Harvard University, spoke on the physiology of efficiency.

Excursions were made to the surrounding country to view some of the numerous archæological remains in this vicinity. Under the guidance of Mr. O. G. S. Crawford and Mr. St. George Gray, the ancient British village and Roman camp on Hod Hill, Ackling Dyke, Worbarrow, Stonehenge, Woodhenge, and other neolithic and later remains were visited. The numerous archæological relics and models of excavations to be found in the Pitt-Rivers Museum at Farnham, Dorset, were also examined, as a preliminary to visiting some of the places from which they were excavated.

Historic Natural Events.

Sept. 28, 1876. Tornado at Cowes.—A rapidly revolving whirlwind, looking like a waterspout or huge funnel, point downwards, approached the south-west shore of the Isle of Wight between Blackgang Chine and the Needles. It passed north-eastwards across the island and reached Cowes between 7 and 8 A.M., doing damage estimated at £10,000 to £12,000. Corn, light articles, and even bricks were dropped on vessels in the Solent, and on the mainland south of Titchfield.

Sept. 29, 1210. Tay Flood.—Cant, in his notes to the Muses' Threnodie, says: "So violent was the torrent that the whole town [of Perth] was undermined, the houses levelled, and many persons of both sexes lost their lives. The Royal Palace [of William the Lion] did not escape. The King's youngest son, John, with his nurse, were carried down the river and drowned, with about fourteen of the Kings domesticks."

Sept. 29, 1538. Formation of a New Volcano.—Monte Nuovo is a conical hill, 440 feet in height above the sea-level, and lies about 8 miles west of Naples. For two years before the eruption that formed it there had been frequent earthquakes in the district that increased in frequency and reached their maximum on Sept. 27-28, 1538. The next day a fissure opened in the ground, from which scoriæ, lapilli, dust, and mud were ejected and, falling round the fissure, gradually formed a hill similar to many others in the district. The eruption died down in about a week, most of the hill having been formed during the first two days.

Sept. 29, 1915. Hurricane in the Gulf of Mexico.—The most intense hurricane in the history of the Gulf of Mexico struck the coast of Louisiana on Sept. 29. At Burrwood, La., the wind reached a velocity of 140 miles per hour in a gust, the highest ever recorded in the Gulf. In New Orleans nearly every building was damaged and several were totally destroyed, and some neighbouring towns and villages were completely wrecked: there were a number of shipwrecks, and the loss of life amounted to 275. This loss would have been far heavier but for the warnings issued by the U.S. Weather Bureau; in fact the greatest individual catastrophe, at Rigolets, resulted from the complete disregard of specific advice.

Sept. 29, 1927. Rainbow Phenomena.—About 4 P.M. seven distinct rainbows were seen simultaneously near Campbeltown in Kintyre. The three interior bows were the brightest, especially the third.

Sept. 30, 1513. Rockfall in Ticino, Switzerland.—A fall of rock from the Pizzo Magno dammed the lower part of the Val Blenio in Ticino. The waters of the river Brenno accumulated behind this dam and drowned the village of Malvaghe, including its campanilo 130 feet high. The dam broke on May 20, 1515, and the valley was entirely devastated, 400 houses destroyed, and 600 persons killed. When the flood reached Lake Langensee immense waves were formed and several shipwrecks occurred.

Sept. 30, 1555. Flood in London.—Holinshed records that "on the last of September by occasion of great wind and rain that had fallen was such great floods that the Kings palace at Westminster and Westminster Hall was overflown with water".

Oct. 1, 1250. Storm in North Sea.—This gale was very violent in the southern North Sea. It is said that the sea flowed twice without ebbing and the noise of the waves was heard a great distance from the shore; at night it appeared to burn as if on fire. Many ships were wrecked, and at Winchelsea, besides the damage to bridges, mills, and dykes, three hundred houses and some churches were drowned owing to the height to which the waters rose. Enormous damage was done in Holland and the marshes of Flanders, where the rivers, choked back by the rise of the sea, overflowed their channels.

Oct. 1, 1899. Whirlwind over Wiltshire.—During the passage of a barometric depression from south-west to north-east across England, a whirlwind or tornado about 2.15 P.M. travelled from south-south-west to north-north-east through Wiltshire, the track having a length of nearly 20 miles but a breadth of only about 100 yards. Many trees were uprooted and a great deal of damage done to buildings.

Oct. 3, 1780. West Indian Hurricane.—A violent hurricane developed to the south of Jamaica on Oct. 2 and travelled northwards across Jamaica, Cuba, and the Bahamas. On Oct. 6 and 7, in about 28° N., 74° W., it wrecked Admiral Rowley's squadron of eight or nine vessels and so moved away to the north-west, doing further damage to a squadron off Cape Henry. The wind and the inrush of the sea entirely destroyed the town of Savanna-la-Mar in Jamaica and several ships were left stranded on dry land; the *Princess Royal*, in fact, was afterwards used as a house. The ground half a mile inland was submerged to a depth of ten feet. The dead lay unburied for weeks, and a pestilence carried off many of the survivors. In the town of Lucea only two houses remained standing, and near Montego Bay four men-of-war were lost.

Oct. 4, 1526. Hurricane at Porto Rico.—According to Dr. Juan de Vadillo, "on the night of Oct. 4 there began on the island of Porto Rico such a storm of wind and rain, here called a hurricane, as to destroy the greater portion of the city of San Juan and to do great damage to the estates in the country by overflowing the rivers".

Oct. 4, 1869. "Saxby's Gale."—In 1868 Lieut. Saxby, a British naval officer, basing his prediction on the supposed influence of the moon, foretold a great storm on Oct. 5, 1869, but without specifying the locality. The storm, accompanied by a very high tide, which crossed New Brunswick, Maine, and Nova Scotia on Oct. 4, was popularly hailed as a verification of this forecast and remembered as "Saxby's Gale".

Societies and Academies.

LONDON.

Institute of Metals (Annual Autumn Meeting at Southampton), Sept. 9.—**D. Hanson**: The use of non-ferrous metals in the aeronautical industry (Autumn Lecture). The present state of aerial transport is in large measure due to the development of suitable alloys and their use in aircraft construction in large quantities. The non-ferrous alloys are strong for their weight, and also possess the advantages that they can readily be used as die-castings, forgings, stampings, and so on, and lend themselves readily to methods of standardised production. Perhaps the most notable feature in regard to aluminium alloys is the extent to which heat-treatment is employed in developing their useful properties. The use of magnesium alloys is of more recent origin, but is rapidly extending. Improvements in melting and casting methods, as well as the discovery of new alloys, have contributed to this extension, and the application of the processes of heat-treatment in suitable instances will probably lead to further improvements.

Sept. 10.—**Ernest A. Smith**: Rolled gold; its origin and development. The paper deals briefly with the history of the rolled-gold industry from its begin-

ning in Birmingham, in 1817, until the present time.—**W. Rosenhain, J. D. Grogan, and T. H. Schofield**: Gas removal and grain refinement of aluminium alloys. A number of selected volatile chlorides have been passed into molten aluminium and certain alloys. All were found to be efficacious in removing dissolved gas from the metal. Some, particularly titanium tetrachloride, also produce a marked reduction in grain-size. The reduction of grain-size occurs also when titanium is added to aluminium in the form of titanium-aluminium alloy produced by the 'Thermit' process. **J. D. Grogan**: Pressure die-cast aluminium alloy test-pieces. The behaviour of selected alloys when subjected to the attack of molten aluminium alloy and the method of entry of metal under pressure into a simple cylindrical mould are described. If certain serious technical difficulties can be overcome, the pressure casting process will yield products of excellent mechanical properties.—**N. W. Ageew and Olga I. Vher**: The diffusion of aluminium into iron. The process takes place in two stages: (1) Solution of iron in liquid aluminium; (2) diffusion of the alloy formed into solid iron. Weiss's law of diffusion has been verified for the binary system iron-aluminium.—**K. L. Meissner**: The artificial ageing of duralumin and super-duralumin. The effect of artificial ageing upon duralumin consists, after an initial softening at lower temperatures, mainly in raising the yield-point, whilst the tensile strength is influenced only slightly. At the same time, the elongation, flexibility, and other cold-working properties are decreased very markedly, and, as shown in previous work, the resistance against corrosion is also decreased. In contrast to duralumin, the tensile strength of super-duralumin (duralumin with addition of silicon) is markedly raised by artificial ageing, but the rise keeps behind that of the yield-point, relatively.—**Wm. L. Fink and Kent R. Van Horn**: Lattice distortion as a factor in the hardening of metals. Rockwell hardness measurements and diffraction patterns showed that lattice distortion can be accompanied by appreciable softening in an externally stressed aluminium alloy ('17 S') or α-brass. Maximum lattice distortion and maximum hardness are not necessarily coincident in age-hardened alloys.—**Marie L. V. Gayler**: A study of the relation between macro- and microstructure in some non-ferrous alloys. The results of a previous investigation are confirmed, namely, the higher the temperature from which an alloy is cast the coarser becomes the macrostructure, and at the same time the microstructure becomes finer, but in a less marked degree. The macro- and microstructure of an alloy do not seem to be affected by various gases, provided the casting temperature is kept low. If, however, the casting temperature is raised, the atmosphere to which the molten metal is exposed has a very marked effect on the macrostructure, together with a small effect on the microstructure; thus hydrogen causes the formation of a fine macrostructure in contrast to that obtained on casting under normal conditions. A copper-aluminium alloy which has been previously freed from gas by the nitrogen process and then melted *in vacuo* still shows inverse segregation. Furnace gases have little effect on the 'modification' of aluminium-silicon alloys. 'Modification' of a silicon-aluminium alloy cannot be obtained by casting into a heavy, water-cooled copper mould.

PARIS.

Academy of Sciences, Aug. 4.—Bigourdan: The astronomical instruments and observations of Bochart de Saron.—**André Roussel**: The general expression of the infinitesimal increase of a function.—**Georges Giraud**: The principal Cauchy integrals and their application to certain problems relating to equations of the elliptic type.—**Thadée Banachiewicz**: The determination of the orbit of Pluto.—**Benjamin Jekhowsky**: The trans-Neptunian planet Pluto.—**Maurice Robert**: Starting low tension dynamos.—**Pierre Chevenard and Albert Portevin**: The influence of reheating on the expansion and hardness of tempered aluminium-silicon alloys.—**J. Perreu**: The measurement of the vapour pressures of aqueous solutions of some hydrated salts. Measurements made by a differential method against water are given for solutions of sodium hyposulphite, sodium sulphate, and manganous chloride.—**Chapas**: The solubilities of some substituted benzoic acids in some chloro-aromatic hydrocarbons.—**Maurice Nicloux**: The determination of oxygen in sea water. A modification of Winkler's method requiring only 5 c.c. of sea water.—**Mlle. Jeanne Lévy and J. Sfiras**: The action of ammonia and of dimethylamine on the ethylene oxides of allylbenzene, phenylcyclohexene and their homologues.—**E. Urion**: The catalytic decomposition of divinylglycol by reduced copper.—**A. Mailhe and Renaudie**: The transformation of ethylene into liquid and solid hydrocarbons. The ethylene was passed over silica gel heated to 700° C.; a complex mixture of hydrocarbons was obtained with boiling points ranging from 75° C. to 330° C.—**Georges Brus and J. Vébra**: The transformation of camphene into isobornyl esters and the decomposition of bornyl and isobornyl esters into camphene. It is shown that the transformation of camphene into isobornyl esters is a reversible reaction, and consequently cannot be quantitative.—**R. Weil**: Observations on quartz.—**H. Derville**: Napoleon marble and its varieties.—**M. Tenani**: The tides of the eastern Mediterranean.—**G. Guittonneau and J. Keilling**: The separation of two soluble sulphur compounds in a soil rich in organic matter. The presence of hyposulphite and pentathionate has been proved.—**J. Risbec**: The duration of evolution in *Æolidia amœna*.—**A. Sartory, G. Hufschmitt, and J. Meyer**: A new mycosis caused by a yeast of the genus *Debaryomyces*: *Debaryomyces mucosus*.—**G. Cuvier and J. A. Carrère**: The action on cancerous subjects of extracts of tumours, administered by the mouth in small doses.

Aug. 11.—The president announced the death of A. J. Le Bel.—**Bigourdan**: Observations and co-ordinates of the Châtillon tower.—**Alayrac**: Extension of the method of conformal representation to movements in three dimensions.—**L. Brillouin**: Electrons in metals and the classification of the corresponding de Broglie waves.—**Louis Natanson**: The variations of relative intensity in the resonance spectrum of selenium.—**René Truchet**: The reaction of organo-magnesium compounds on the aryl sulphonchlorides. The principal reaction is $ArSO_2Cl + RMgX = Ar.SO_2.MgX + RCl$, the author confirming the work of Gilmann and Fothergill.—**P. Mondain-Monval and B. Quanquin**: The formation of peroxides in the direct oxidation of hydrocarbons by air. Hydrocarbons (pentane, hexane, octane) mixed with air and passed through a tube kept at 300° C. give, besides aldehydes and carbon dioxide, a yellow oily substance. This oil gives the reactions of a peroxide of the type of the methyl hydroperoxide of Rieche and Hitz, $CH_3.O.O.H$.—**G. Chalaud**: The first phases of the development of the gametophyte in *Lophocolea cuspidata* and in *Chiloscyphus polyanthus*.

Aug. 18.—**G. Bigourdan**: The observations of Méchain and of Saron. The co-ordinates of the Observatory of Colombes.—**Ch. Achard and M. Hamburger**: The proteins of the blood serum in some

anæmic conditions. Details of ten cases giving the number of red corpuscles, total proteins, serine, globuline, and, in five cases, the myxo-protein. In pernicious anæmia the diminution in the number of red corpuscles is always accompanied by a reduction in the serum proteins, and the latter increase when the number of red corpuscles goes up under treatment.—**Ch. Achard** and **I. Ornstein**: Some constituents of blood-serum in myxœdema. Analytical details of twelve cases.—**C. Gutton** and **E. Pierret**: Radiotelephonic transmission on waves of 17 cm. length. Details of apparatus giving successful transmission over a distance of 6·8 km.—**Edouard Callandreau**: Remarks on the elastic line of a bar loaded at one end.—**Albert Portevin** and **Etienne Pretet**: The influence of deformation on forging or hot rolling on the mechanical properties of steel.—**Thadée Banachiewicz**: A new method of determination of the orbit of a trans-Neptunian planet.—**A. Bogros**: The saturated vapour pressure of lithium. A modification of Knudsen's effusion method was employed; vapour pressures for six temperatures between 510° C. and 572° C. are given.—**Ny Tsi Zé**: The influence exercised by the X-rays according to F. Allison on the magnetic rotatory polarisation and on the properties of inactive liquids. In a field of 21,000 gauss, no confirmation of Allison's effect could be obtained with water, carbon disulphide, or nitrobenzene.—**A. Cotton**: Remarks on the preceding communication.—**B. Nitikin** and **L. Komleff**: The amount of radium in the petroleum waters of Baku and Daghestan.—**Mme. Pierre Curie** and **Georges Fournier**: A relation between the disintegration constant of radioactive elements emitting α-rays and their capacity of filiation.—**M. Prettre, P. Dumanois**, and **P. Laffite**: The oxidation and inflammation of mixtures of pentane and air. This hydrocarbon shows two points of inflammation, one between 260° C. and 300° C., the second between 660° C. and 670° C. In the first interval the gas mixture shows a blue flame, which disappears when the temperature is raised above 300° C.—**L. Bert** and **P. Ch. Dorier**: A new method of synthesis of cinnamic aldehyde and its homologues.—**Pan Tcheng Kao**: The micrography of piezoelectric quartz.—**E. Rothé, J. Lacoste**, and **Mlle. J. Roess**: Earthquakes in France in 1928 and 1929. Details concerning five earthquakes in 1928 and eight in 1929.—**Pierre Dangeard**: A labile iodo-complex produced by Laminaria.—**Marc de Larambergue**: The cytology of the autofertilisation of *Bullinus contortus*.—**H. Pénau** and **D. Santenoise**: The isolation and preparation of vagotonine, a new pancreatic hormone.—**E. Ducloux** and **Mlle. G. Cordier**: The study of certain humoral modifications arising in the course of experimental bovine marginal anaplasmosis.—**C. Labailly, G. Desbouis**, and **A. Voulland**: An efficacious method of treatment of one of the most widespread causes of infantile mortality in crèches: pneumococcic infection.—**F. Vlès, A. de Coulon**, and **J. L. Nicod**: New researches on the treatment of tar tumours in mice by certain amino-acids.—**Mme. N. Dobrovolskaia-Zavadskaia**, and **N. Kobozieff**: The lethal factor accompanying anuria and brachyuria in mice.

ROME.

Royal National Academy of the Lincei, April 27.

U. Cisotti: Isotropic tensors.—**M. La Rosa** and **L. Sesta**: A two-valve circuit emitting trains of discontinuous waves. The mode of action of a two-valve circuit coupled with a resistance amplifier is considered.—**G. Barba**: The functional equation $f(x).f'(x) - f[f(x)]$ related to a geometrical problem (2). The analytical solution to the problem of determining the form of the intrinsic equation of a curve in order that this may be similar to its own evolute is now considered in relation to the initial geometrical problem.—**F. Sbrana**: Characteristic properties of the infinitesimal operation in the group of derivations.—**G. Krall**: A general method for the approximate evaluation of the critical loads for beams of any type whatever.—**G. Natta**: The crystalline structure of hydrogen sulphide and hydrogen selenide (2). By means of the powder method and with the help of a special spectrograph adapted for low temperatures, it is found that at $-170°$ solid hydrogen selenide possesses a cubic unit cell of side $6·020 \pm 0·005$ A. and volume $218·2 \times 10^{-24}$ c.c., containing four molecules; the calculated density is 2·456. Hydrogen sulphide and hydrogen selenide exhibit analogous lattices of the fluorite type (spacial group, O_h5). Given the analogies in the structure and in the lattice dimensions of these two compounds, their perfect isomorphism may be anticipated. In calculating the intensities of the lines of the photograms of the compounds, better agreement with the experimental intensities are obtained on the assumption of an ionic structure.—**A. Ferrari** and **C. Colla**: Chemical and crystalline structures of certain complex nitrites. The triple nitrites of potassium and lead with copper, nickel, and cobalt respectively form monometric crystals, the unit cell containing four molecules. The values of a and of the calculated density are: $K_2PbNi(NO_2)_6$, 10·55 A., 3·50; $K_2PbCo(NO_2)_6$, 10·49 A., 3·66; $K_2PbCu(NO_2)_6$, 10·52 A., 3·56. The lattice of potassium cobaltinitrite is cubic and of the same type as the preceding: a 10·32 A., calculated density 2·73; the water found on analysis is probably water of impregnation of the lattice and not true water of crystallisation.—**C. Andreatta**: Bianchite, a new mineral. This mineral, which occurs on the goslarite of an artificial grotto of the Raibl mine, represents a new species of natural hydrated sulphate of the composition $FeSO_4$, $2ZnSO_4$, $18H_2O$. No distinct crystals were obtainable, but the compound appears to crystallise in the monoclinic system. The degree of hydration of the mineral under different conditions has been studied.—**A. Belluigi**: Physical characteristics of the marginal Apennine plain of Modena.

Diary of Societies.

WEDNESDAY, OCTOBER 1.

SOCIETY OF PUBLIC ANALYSTS (at the Chemical Society), at 8.—G. W. Baker: Scientific Evidence relating to Firearms, with Special Reference to a Recent Murder Trial. (As the author cannot be present, Mr. G. H. Perry has kindly consented to read the paper and to demonstrate the evidence.)—J. W. Croxford: The Composition of Rye Oil.—G. E. Lester Smith: The Determination of Unsaponified Oil in Soap or Fatty Acids.

THURSDAY, OCTOBER 2.

SOCIETY OF CHEMICAL INDUSTRY (Bristol Section) (in the Chemical Department, The University, Bristol), at 7.30.—Prof. J. W. Hinchley: Air and Water.

FRIDAY, OCTOBER 3.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—S. J. Crispin: The Development of the Bridge.

SATURDAY, OCTOBER 4.

ROYAL SANITARY INSTITUTE (in the Assembly Room, Town Hall, Hereford), at 10.—Councillor Mrs. Luard: The Place of Women in Local Government.—G. H. Jack: The Preservation of the Countryside.—Councillor J. R. Barker: The Health Authority and the Milk Supply.

INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch) (at the College of Technology, Manchester), at 4.—R. W. Stubbs: Presidential Address.

MONDAY, OCTOBER 6.

SOCIETY OF ENGINEERS (at Burlington House, Piccadilly), at 6.—Lieut.-Col. H. C. Hawkins: Some Impressions of America.

IRON AND STEEL INSTITUTE (Joint Meeting with the Cleveland Institute of Engineers) (at the Cleveland Technical Institution, Middlesbrough), at 7.30.—H. C. Wood: Open-hearth Furnace Steelworks: a Comparison of British and Continental Installations and Practice.—J. Šarek: What Reasons compelled the Prague Ironworks to Introduce Thin-walled Blast-furnaces.—A. Kříž: The Heterogeneity of an Ingot made by the Harmet Process.—L. W. Schuster: The Effect of Contamination by Nitrogen on the Structure of Electric Welds.—O. Quadrat: A Contribution on the Problem of the Analysis of Basic Slags and the Representation of their Composition in a Triangular Diagram.

TUESDAY, OCTOBER 7.

INSTITUTE OF METALS (Birmingham Local Section) (in Chamber of Commerce, Birmingham), at 7.—T. G. Bamford: Chairman's Address.

IRON AND STEEL INSTITUTE (Joint Meeting with the Lincolnshire Iron and Steel Institute) (at the Secondary Schools, Doncaster Road, Scunthorpe), at 7.—F. Bainbridge: Developments in Fuel Economy at Skinningrove.—J. A. Jones: Chromium-Copper Structural Steels.

IRON AND STEEL INSTITUTE (Joint Meeting with the Sheffield Metallurgical Association) (at 198 West Street, Sheffield), at 7.30.—D. F. Campbell: High-Frequency Steel Furnaces.—W. H. Hatfield: Permanence of Dimensions under Stress at Elevated Temperatures.—A. Kříž: The Heterogeneity of an Ingot made by the Harmet Process.—H. C. Wood: Open-hearth Furnace Steelworks: a Comparison of British and Continental Installations and Practice.

WEDNESDAY, OCTOBER 8.

ILLUMINATING ENGINEERING SOCIETY (at 15 Savoy Street, W.C.2), at 6.30.—Report on Progress in Illuminating Engineering, and Display of Exhibits illustrating Recent Developments in Illumination.

INSTITUTION OF CHEMICAL ENGINEERS (in the Chemical Society's Rooms), at 8.—Dr. Saral J. Kohli: The Effect of Surface Conditions on Heat Transmission.

THURSDAY, OCTOBER 9.

ROYAL AERONAUTICAL SOCIETY (in the Lecture Hall of the Royal Society of Arts), at 6.30.—C. R. Fairey: The Growth of Aviation.

INSTITUTE OF METALS (London Local Section) (at Society of Motor Manufacturers and Traders, Ltd., 83 Pall Mall), at 7.30.—W. T. Griffiths: Chairman's Address.

INSTITUTION OF WELDING ENGINEERS (at the Engineers' Club, Albert Square, Manchester), at 7.45.—J. Ryder: The Training of Operators in the Welding and Cutting Industries.

FRIDAY, OCTOBER 10.

ROYAL SANITARY INSTITUTE (in the Guildhall, Nottingham), at 4.30.—Alderman A. R. Atkey: River Pollution.—Dr. L. P. Lockhart: Industrial Medicine in Relation to Public Health.

IRON AND STEEL INSTITUTE (Joint Meeting with the Local Branch of the South Wales Institute of Engineers) (at the Royal Metal Exchange, Swansea), at 7.—A. Kříž: The Heterogeneity of an Ingot made by the Harmet Process.—H. C. Wood: Open-hearth Furnace Steelworks: a Comparison of British and Continental Installations and Practice.—O. Quadrat: A Contribution on the Problem of the Analysis of Basic Slags and the Representation of their Composition in a Triangular Diagram.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—S. Dunlop: The Refining of Cane Sugar.

INSTITUTE OF METALS (Sheffield Local Section) (in Non-Ferrous Section, Applied Science Department, University, Sheffield), at 7.30.—Conjoint Meeting for the Sixth "Sorby" Lecture.

SATURDAY, OCTOBER 11.

INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch, Burnley Section) (at the Technical College, Burnley). F. Griffiths: Belgian Moulding Sands in the Iron Foundry.

PUBLIC LECTURES.

MONDAY, OCTOBER 6.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Prof. W. H. Park: Pneumonia: The Types of Pneumococci in Adults and Children and their Significance (Harben Lecture 1).

TUESDAY, OCTOBER 7.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Prof. W. H. Park: Pneumonia: The Epidemiology; the Refining of Antipneumococcus Serum (Harben Lecture 2).

KING'S COLLEGE, LONDON, at 5.—Dr. J. W. Pickering: Blood Plasma and Platelets. (Succeeding Lectures on Oct. 14, 21, and 28.)

WEDNESDAY, OCTOBER 8.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Prof. W. H. Park: Pneumonia: The Therapeutic Use of Vaccines and Antibacterial Sera (Harben Lecture 3).

THURSDAY, OCTOBER 9.

KING'S COLLEGE, LONDON, at 5.15.—Rev. Dr. N. Sykes: The Age of Reaction and Reconstruction (1815-65).

UNIVERSITY COLLEGE, LONDON, at 5.30.—Prof. H. Spemann: Introduction to the Theory and Practice of Experimental Embryology (in English). (Succeeding Lecture on Oct. 10.)

CONGRESS.

SEPTEMBER 29 TO OCTOBER 1.

FARADAY SOCIETY (in Laboratory of Physical Chemistry, Cambridge).—Discussion on Colloid Science applied to Biology.

Monday, Sept. 29, 2 to 4 and 4.30 to 7.—Equilibrium in Protein Systems. In Chair—Sir William Hardy, who will introduce the Discussion.

Prof. A. V. Hill: Membrane-Phenomena in Living Matter Equilibrium or Steady State.

Dr. R. A. Gortner: The State of Water in Colloidal and Living Systems.

Prof. E. J. Bigwood: Distribution of Diffusible Ions in Gels.

Prof. W. Pauli: The Behaviour of Proteins towards other Colloids and towards Electrolytes.

Prof. F. F. Nord: The Biological Significance of the Physical Influence of Gases on Colloids.

Tuesday, Sept. 30, 10 A.M. to 11.15 A.M., 11.30 A.M. to 1 P.M., 2.30 to 4, and 4.30 to 7; and

Wednesday, Oct. 1, 10 A.M. to 1 P.M.—In Chair—Sir F. Gowland Hopkins, who will introduce the Discussion.

Dr. Honor B. Fell and Dr. Wilmer, followed by Kinematograph Studies of Living Cells by Dr. Canti: The Structure, Behaviour and Physiological Characteristics of Vertebrate Cells cultivated *in vitro*.

Prof. E. Faure-Fremiet: The Kinetics of Living Matter.

Prof. R. A. Peters: Surface Structure in the Integration of Cell Activity.

Prof. O. Warburg: Surface Reactions in Living Cells.

Prof. H. Pfeiffer: Isoelectric Point of Cells and Tissues.

Dr. A. von Muralt and Dr. J. Edsall: Double Refraction in Protein Systems.

Dr. J. H. Quastel: The Mechanism of Bacterial Action.

Other speakers will be: Prof. E. F. Burton, Prof. J. Duclaux, Prof. H. Euler, Prof. H. Freundlich, Prof. H. R. Kruyt, Prof. H. Lundegardh, Dr. P. Lecomte du Nouy, Prof. W. J. V. Osterhout, Prof. Wo. Ostwald, Prof. and Mme. Jean Roche, Dr. Straub, and Prof. T. Svedberg.

SATURDAY, OCTOBER 4, 1930.

Science and Society.

Among the subjects discussed at the recent meeting of the British Association, few have attracted so much interest or comment as the relation of science to unemployment and to labour. The question was fairly raised in Prof. T. E. Gregory's presidential address on "Rationalisation and Technological Unemployment", and his assertion that rationalisation, one of the most popular remedies for unemployment, may in itself be one of the causes producing the evil, was not seriously challenged in the discussion which followed. If, therefore, we have to admit that the elaboration of scientific methods of production and management is increasing, even if temporarily, the volume of unemployment, it is at least intelligible that labour should be dubious about acknowledging or accepting that leadership of science which we have frequently discussed in these columns.

There is, indeed, in the present situation much to excuse a passing reflection that perhaps, after all, the people of Erewhon were wiser than ourselves in destroying their machines, lest, as Marx predicted, the machines reversed the original relation and the workmen became the tool and appendage of a lifeless mechanism.

There is a popular fallacy, to which Sir Richard Gregory alluded in his recent address to the Bristol branch of the Independent Labour Party, which regards science as synonymous with mechanical invention, and therefore as largely responsible for the mechanisation of the age and its attendant evils. From this point of view the undoubted increase in the volume of unemployment which has accompanied the improvement of the means of production may well be regarded as a high price to pay even for the elimination of some of the grosser forms of labour to which in the past men were compelled to submit. To-day in the Ruhr ninety per cent, and in Belgium eighty per cent, of the coal produced is mined with pneumatic picks, and the mine of the future will probably be a brilliantly illuminated underground workshop, operated by electricity, the miner a skilled mechanic. The magnetic crane enables a workman to operate from a control-house at one time tons of pig-iron which formerly men handled in discomfort, pig by pig. The comfort and the welfare of the few, on this view, may, however, be too dearly purchased when we consider the lot of the displaced workers, and perhaps still more the repression of individuality and the retarded development which, as Marx predicted, have often accompanied mass production. Moreover,

although, contrary to prediction, the hours of labour have been shortened and not lengthened, and the standard of living has been raised considerably, in the modern Press, and in certain phases of broadcasting and the cinematograph, mechanical science has tended to project its mechanising influence into hours of leisure and intensify that mechanisation of the mind which is one of the symptoms and evils of our age.

If science, therefore, were nothing but mechanical invention, it would not be easy to plead that civilisation requires not less but more science in the control of affairs. The truth is that inventive ingenuity has often little in common with science, and even in the case of mechanical science, which is only one branch of science, unsatisfactory social conditions are a consequence not of scientific discoveries and advances, but of incapacity to use them aright. On the other hand, the discoveries with which in every branch of science scientific workers are most closely associated are creative discoveries, and these are responsible not for displacing labour, but for creating new demands and new industries in which labour is absorbed. Nearly a hundred years ago the discoveries of Faraday in the laboratory of the Royal Institution provided the fructifying idea which soon bore fruit as the dynamo. From these purely scientific discoveries has developed the vast electrical engineering industry, which in its light, power, and traction companies, electrochemical plant, and the companies manufacturing electrical equipment and apparatus, provides employment for millions of workers.

The radio industry is similarly the outcome of the scientific researches of Maxwell and of Hertz on the properties of electromagnetic waves, and the film industry, the automobile industry, the rayon, the aircraft, and the synthetic ammonia industries are all the result of fundamental scientific investigations, the practical importance of which was undreamt of at the time. Yet to-day, as Dr. Little pointed out in his presidential address to the Society of Chemical Industry at Manchester last year, each of these industries employs thousands of workers, reaching more than four million in the case of the automobile industry.

It is to creative science that society must look for the best hope of an ultimate solution of the unemployment problem. Indirectly, therefore, the problem of unemployment is linked with the problem of fostering the most vigorous intellectual activity among scientific workers and attracting into the service of science the most able minds the present generation can provide. Conditions which tend to lower the standard of recruitment for the various branches of the profession of science may react dangerously upon the welfare of the community. If full contact is secured between the finest type of such scientific work and industry, a fertilisation of industrial research will result from which all branches of the community must and will benefit.

So competent an observer as Prof. Henry Clay remarks in this connexion that industrial expansion takes place less as the result of the establishment of entirely new firms to exploit new processes and new demands than as a result of existing firms, which are making profits by the efficiency of their management, applying these profits to finance expansion in new directions. It would seem that only through the rationalisation of industry can creative science exert its full influence in expanding employment.

It is significant that the recent Trades Union Congress has shown some appreciation of this fact, and in his presidential address Mr. John Beard pointed out that the unemployment situation must be judged in relation to the last quarter of a century's concentration upon invention and scientific discovery. Mr. Beard went on to urge the need of a bolder, more *scientific*, and more energetic attack on the problem of unemployment than had been thought of so far. The emphasis placed upon industry rather than upon politics by this Congress encourages the hope that labour will tend more to assist in the process of industrial growth and not limit its discussions to the distribution of profits.

The more carefully the problem is considered, the clearer it becomes that defective leadership is largely responsible. Over-production is not so much a necessary consequence of the more rapid and abundant production of goods made possible by scientific invention as of the errors in judgment on the part of those who assumed the risks and direction of industry. Prof. Henry Clay, in the discourse before the Royal Institution to which we have already referred, described over-production as the production of more than can be sold at the price anticipated when production was undertaken, and points out the effect of such failure in checking further production.

Such failures in judgment must not, however, necessarily be interpreted as involving culpable negligence on the part of those responsible. They are merely an example of the far-reaching effect of human mistakes in industry and in politics to-day. Society probably still suffers less from the evil

wrought by heartlessness than from the inability of the individual human factors to comprehend the complexities of the situations and their reactions in a world which science in one sense has bound so closely together. Modern technical achievement and scientific thought foreshadow a new economic structure for society, and the greatest danger to civilisation to-day is the divorce between science and politics. There is little hope for society unless its political institutions are sufficiently elastic to allow scientific and technical knowledge to exercise decisive influence upon the major policies of the State.

Modern society suffers from two evils, of which the unemployment problem is only one symptom. The first is its inability to control the results of its own thinking, as exemplified in the achievements of modern science, pure and applied. A main task of our epoch is the reconciliation of industrial and political practice with progressive scientific thought. Neither the disarmament problem nor the unemployment problem, for example, would present the same problem in the world to-day if the scientific thought, the application of which has revolutionised the conditions of warfare and of industry, exercised its proper and rational influence in political and diplomatic quarters. Fulfilment of such tasks involves wise direction of mechanisation, and this is the fundamental case for scientific management. The freer the play of creative scientific thought, the easier industry in particular and society in general will find the transition or adjustment to reasonable social conditions under the impact of the new economic forces.

Perhaps still more important is the contribution of creative science to the amelioration of that other evil of society, the mechanisation of mind, which, originating under the conditions of mass production, is often perpetuated into the hours of recreation by such agencies as the Press, the cinema, and even broadcasting. The loss of the power of self-amusement, the absence of the knowledge of the right use of its increased leisure, are characteristic of the age, and there is no more urgent duty than the encouragement of individualism. The fountain-heads of human progress, from Plato onwards, have been the fundamental thinkers, and the problem is not only to bring thought of this quality into closer touch with public affairs, but also to enable the common man to appreciate more vitally the quality of such thinking. The more standardised the conditions of labour become for the mass of mankind, the less the demand for handicraft and the creative spirit during the hours of employment, the more important it is for society that the common man should be stimulated to self-expression in his hours of leisure.

The application of that stimulus may not be left to art alone. Science must bring to sociology that spirit of adventure and experiment which have ever led to those great creative discoveries from which mankind has reaped the greatest benefit, whether of thought or of action. The most startling and successful pieces of reconstruction in the post-War world have resulted from the handling of complicated economic, social, and international problems along new rational and scientific lines. Efficient organisation is an indispensable factor in human progress to-day, but originality of thought and character are still its mainsprings. Such thought and such character can bring into the rationalisation movement to which industry is bound that humanising influence and elasticity which can make it the liberator and benefactor of industry and not its tyrant.

If there is a sense in which science, through the uncontrolled development of its mechanical applications, has seriously threatened the physical and mental development of man, it is still to the free play of creative scientific thought in industry, in politics, in society, that we must look for the liberation of man from mechanisation and for the control of the material and economic forces in his environment which at times assume such threatening proportions. In truth, science, after liberating the world from the thraldom of baser superstition and the irrational fear of natural phenomena, has made the continued expression of certain of man's acquisitive and combative instincts in industrial and international rivalry inconsistent with the safety of civilisation. It has now the task of revealing to man the channels in which his instincts and individuality can find a safer and a finer expression in co-operation in the exploration of yet unravelled secrets of Nature, the conquest of disease, and of those other factors in his environment which still take their toll of human life and happiness.

It is creative science which must lead society in that search of truth for the control of Nature and transformation of matter for the service of mankind, the liberation of the human spirit from ignorance, superstition, and slavery to the forces of Nature, and the reformation of social and political institutions for the benefit of the greatest number, which Hu Shih declared to be the characteristic of an ideal and spiritual civilisation.

Letters to the Editor.

A New Phenomenon in the Change of Resistance in a Magnetic Field of Single Crystals of Bismuth.

FROM many investigations it is well known that bismuth shows very variable behaviour. We have investigated a very pure specimen; Hilger's bismuth was purified still further. The crystals made from this material proved to be excellent. With X-rays they show very sharp interference spots or lines, and when compressed nothing could be observed of the phenomenon of 'cracks' as described by Borelius, Lindh, and Kapitza (*Proc. Roy. Soc.*, A, vol. 119, p. 366; 1928). From these crystals we measured the change of resistance in the magnetic field at different temperatures.

First we determined the change in resistance of several crystals having the principal axis parallel to their length. The current flows in the length direction of the crystal. The rod is put in the magnetic field with its length (that is, principal axis) at right angles to the lines of force of the field, and it is possible to turn it round an axis coinciding with the principal axis.

We determined the curves giving the change of resistance as a function of the intensity of the magnetic field, when one of the binary axes was either parallel to or at right angles with the field. These curves show a very complicated form, extremely so if the binary axis is at right angles with the field.

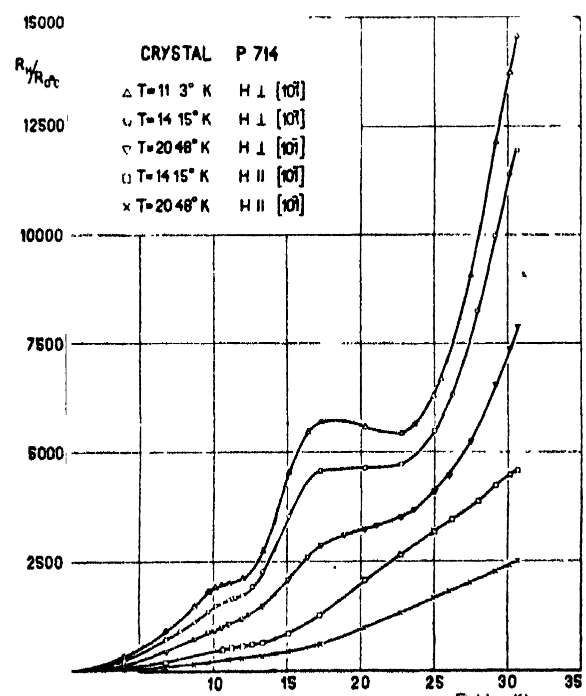

FIG. 1.

In Fig. 1 these curves are given for the temperatures 20·48° K., 14·15° K. and 11·3° K. The abscissæ are the intensities of the magnetic field; the ordinates are the values of $R_H/R_{0°\,C.}$ R_H is the resistance in the magnetic field at low temperatures; $R_{0°\,C.}$ the resistance without a field at 0° C. It will be seen that the curves do not show a parabolic part in the beginning which gradually changes into a linear part at higher field strengths. It has been found that the whole phenomenon strongly depends on temperature: at higher temperatures the curves become more and more simple. This can already be seen at 20·48° K. Here the first flat part found at about 9·5 kilogauss, and prominent at 11·3° K., has nearly disappeared. Measurements at higher temperatures, for example, 64·25° K. and 77·40° K., show a very simple curve, just as has been found hitherto at all temperatures.

In order to investigate the phenomenon more thoroughly we measured the change of the resistance, keeping the field constant, but changing gradually the angle between a binary axis and the lines of force, and

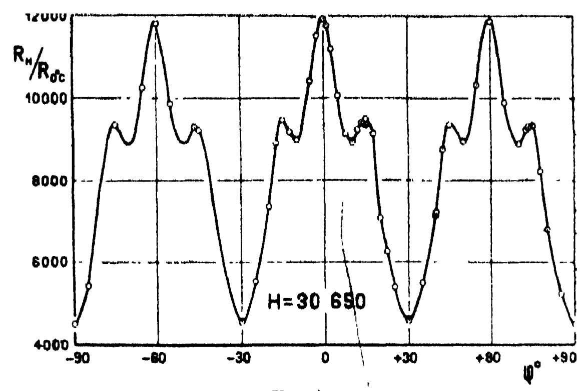

FIG. 2.

reading the resistance and the angle after each displacement. In Fig. 2 the abscissæ are the angle ϕ, between the crystallographic direction [112] in the crystal and the lines of force, ordinates are the values of R_H/R_{0} C. at those different angles, in a field of 30·650 gauss at a temperature of 14·15° K. This curve does not show cosine form, but gives a much more complicated relation of the resistance to small changes of the angle. Simple cosine curves have been found only at very low field strengths. At higher temperatures we do not find the complicated form.

We are now investigating some crystals having two different orientations. Both these orientations have the principal axes at right angles with the length of the crystal. For the first orientation, the length coincides with the direction of a binary axis (and with the axis round which the crystal can be turned, it being also at right angles with the lines of forces and coinciding with the direction of the current). For the second one all this is the same, but the length coincides now with the direction of a bisectrix of two binary axes. Here, too, we investigated the change of resistance with temperature, field strength, and angle of the principal axis with the field. The most important result of these investigations is that the curves have much in common with those given above for the other orientation (Figs. 1 and 2).

Here, too, we find at low temperatures that the resistance in the field changes rapidly with small changes of ϕ. This phenomenon disappears only when we pass to high temperatures and to weak magnetic fields. Of course the form of the curve giving $R_H/R_{0°}$ C. as a function of ϕ is in this case quite different from the one given in Fig. 2.

The results are very much influenced by the purity of the material used for the crystals. As an indication of this purity, it may be stated that our crystals show at 1·3° K. a resistance having a value of some thousandths of that at 0° C. At 11·3° K. the resistance in a magnetic field of 31 kilogauss is 922·000 times higher than that without the field.

Intensity of Total Scattering of X-Rays by Monatomic Gases.

RAMAN (*Indian J. of Phys.*, **3**, 357; 1928) and A. H. Compton (*Phys. Rev.*, **35**, 925; 1930) have calculated according to classical electrodynamics the scattering of X-rays by an atom in which the electrons are arranged with random orientation and with arbitrary radial distribution. The intensity of the X-ray scattered at an angle θ to a distance R is given by

$$I_\theta = \frac{Ie^4(1+\cos^2\theta)}{2m^2R^2c^4}\left\{Z + (Z^2-Z)\left[\int_0^a 4\pi r^2 p(r)\frac{\sin kr}{kr}dr\right]^2\right\} \qquad (1)$$

where I is the intensity of the primary beam, $k=(2\pi/\lambda)\sin\frac{\theta}{2}$, $4\pi r^2 p(r)$ is the probability that any electron shall lie between r and $r+dr$ from the nucleus, a is the maximum radius of the atom, and Z, e, m, and c have their usual significance. In comparison with Wentzel's theory of X-ray scattering, Compton has separated I_θ into two parts, namely, I_1 representing the intensity of coherent scattering and I_2 the intensity of incoherent scattering, where

$$I_1 = \frac{Ie^4(1+\cos^2\theta)}{2m^2R^2c^4}Z^2F^2, \qquad I_2 = \frac{Ie^4(1+\cos^2\theta)}{2m^2R^2c^4}Z(1-F^2),$$

and
$$F = \int_0^a 4\pi r^2 p(r)\frac{\sin kr}{kr}dr.$$

Raman (loc. cit.) has come to the same conclusion from simple classical considerations. When corrected for the change of wave-length, equation (1) becomes (cf. Compton, loc. cit.)

$$I'_\theta = \frac{I_2}{[1+\gamma(1-\cos\theta)]^3} + I_1 \qquad (2)$$

where $\gamma = h/mc\lambda$. We expect this formula to give a closer approximation to the intensity of the total scattering.

If instead of the probable position of a single electron, we regard $4\pi r^2 Zp(r)dr$ as the probable number of electrons between r and $r+dr$, we see therefore that the calculation of the intensity of the total scattering depends entirely on the evaluation of the radial charge distribution of the electrons in the atom. It is well known that Thomas (*Proc. Camb. Phil. Soc.*, **23**, 542; 1927) and Fermi (*Zeit. f. Phys.*, **48**, 73; 1928) have independently derived an approximate expression for the charge distribution of the electrons in the atom by considering the electrons as a degenerate gas surrounding the nucleus, an idea which seems to be in accordance with the atomic model postulated by Raman and Compton in deducing equation (1). If the charge density of the electrons in the atom evaluated by the Thomas-Fermi method is substituted in place of $Zp(r)$ in equation (2), the intensity of the total scattering for any scattering angle can be numerically calculated. Owing to the interference effect due to neighbouring atoms in diatomic molecules, we expect equation (2) to be directly applicable only to the scattering of X-rays by monatomic gases and vapours. A calculation has been made of the intensity of the scattering of X-rays by helium and argon, and the results are compared with the experimental data recently obtained by Barrett (*Phys. Rev.*, **32**, 22; 1928) in Fig. 1, where the scattering per electron is plotted against the scattering angle θ.

While the curve I represents the scattering from helium for a wave-length equal to 0·49 A., the curves II and III represent the scattering from argon for wave-lengths equal to 0·40 A. and 0·48 A. respectively. The classical theory of J. J. Thomson for the scattering from a single electron is plotted as the broken curve marked C. Since Barrett's measurements give relative values of scattering per electron for different angles and for different gases, but not absolute values, so in each case the experimental data have been multiplied by an arbitrary factor throughout. It is seen that the agreement between theory and experiment seems to be satisfactory.

Recently Waller and Hartree (*Proc. Roy. Soc.*, A, **124**, 119; 1929) investigated theoretically the intensity of total scattering of X-rays by atoms of a monatomic gas on the basis of quantum mechanics. For the case of argon a strict comparison of their

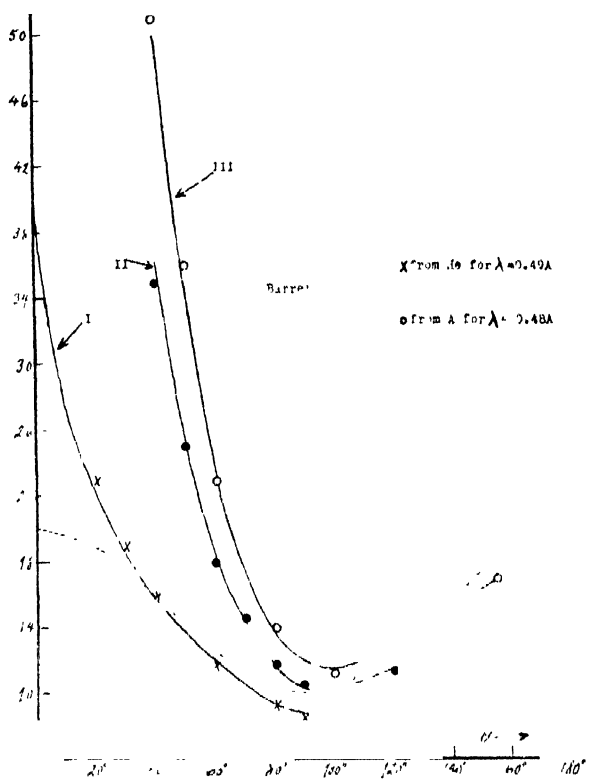

FIG. 1.

calculation with Barrett's results seems not to be possible. This is ascribed by these authors to the fact that the wave-lengths used by Barrett are rather short, so that for the experimental results 'relativity effects' are appreciable, whereas in their derivation of the theoretical formula these effects are completely neglected. A comparison of Waller and Hartree's results for argon with those of the present calculation indicates that the absolute value of the intensity of scattering per electron for the large angle of scattering given by Waller and Hartree is much higher than that calculated according to equation (2). Unfortunately, no experimental data are available to decide this point. Moreover, owing to the factor introduced to correct for the change of wave-length, equation (2) shows that the quantity R defined by Waller and Hartree is not a function of $\sin\frac{\theta}{2}/\lambda$ only, a result not in agreement with the conclusion drawn by these authors.

Finally, it may be remarked that by the method outlined above the scattering by all monatomic gases and vapours can be approximately estimated. I have evaluated numerically the scattering from helium,

argon, neon, krypton, sodium, potassium, and mercury for molybdenum $K\alpha$ and copper $K\alpha$ radiation and experiments are in progress to test these results.

A detailed account of this work will be published elsewhere.

Raman Effect in Hydrogen Sulphide.

THE Raman spectrum of hydrogen sulphide, both in the gaseous and liquid states, has been successfully photographed by me. The liquid exhibits a single intense and quite sharp line shifted by 2578 wave-numbers from the exciting mercury radiation. With the gas, the line appears in a slightly different position, with a frequency shift of 2615 wave-numbers, and is distinctly more diffuse than in the liquid. According to Barker and Meyer (*Trans. Far. Soc.*, **25**, 912; 1929) the infra-red absorption spectrum of gaseous hydrogen sulphide shows a complex band at about $3\cdot7\,\mu$ which evidently represents the superposition of rotation on this vibrational frequency. The plates for both the liquid and the gas showed indications of other faint lines or bands which were adjacent to the exciting mercury radiations and presumably could be ascribed to a rotational Raman effect. It may be remarked that the line observed with the liquid hydrogen sulphide is identically in the same position as a prominent line obtained in the Raman spectra of a series of organic hydro-sulphides studied at Calcutta by Venkateswaran, and also in its frequency shift with an important infra-red absorption frequency of these compounds.

Pearl-like Object found in a Prawn.

IN 1910 Prof. F. H. Herrick, of the Western Reserve University, Cleveland, brought to the notice of the scientific world, through the columns of the *American Naturalist* (vol. 44, pp. 294-301), the very interesting find of a pearl-like structure embedded in the muscles inside the claw of a lobster. The object, which was believed to be unique, was first examined by some pearl dealers, and declared to be a true 'lobster pearl'. It was more or less spherical, with one flat side, and was 11 mm. in diameter. Its specific gravity was 1·45 and hardness 'about 3'. After a careful examination of the object, Prof. Herrick came to the conclusion that the 'pearl' was only an ingrowth of chitin due to some "vagary of the process of regeneration".

Recently a similar 'pearl' has been brought to me by Mr. D. D. Mukerji, of the Zoological Survey of India. It was really discovered by his sister, Miss Jutheca Mukerji, who, while eating a prawn (a small Peneid), felt something hard between her teeth. As only the abdominal region of the prawn is eaten, it seems evident that the 'pearl' must have been embedded in the thick abdominal muscles.

The 'pearl' is spherical in shape, with slight protuberances and hollows. There are two or three fairly large irregular depressions on the surface, but these are probably due to some mechanical cause, perhaps to the action of the teeth while the prawn was being eaten. The 'pearl' is more or less uniformly round, without any flat pole. It is slightly less than 3 mm. in diameter and its absolute weight is 0·0174 gm. Its specific gravity is about 1·32 and the refractive index 1·558. It is practically colourless and has a somewhat pearly lustre. It is transparent and has no nucleus. Its hardness is about 2·5. Dr. J. A. Dunn, Curator, Geological Survey of India, who has kindly measured the specific gravity, refractive index, etc., for me, is of the opinion that it is made of material which "grew radially from the centre, the crystalline direction radiating outwards from the centre, so that the sphere shows a dark cross between crossed nicols, which rotates with the nicols, analogous to a radiating fibrous mineral". On a careful examination the 'pearl' appears to be formed of close concentric layers. The outer surface is covered throughout by extremely fine meridional striations, and in places, when the outer layer is broken, the striations can be seen on the inner strata also. Another remarkable feature of the 'pearl' is that it is apparently some-

FI . 1.—Pearl-like object (enlarged) from a prawn.

what porous. In the course of the specific gravity tests, spread over two or three days, it absorbed 0·0004 gm. of water, the weight returning to normal (0·0174) on its being allowed to dry.

There seems to be scarcely any doubt that the 'pearl' is made of chitin, similar to the hard shell of the prawn. Sollas has shown (*Proc. Roy. Soc. London* (B), 79, pp. 474-481; 1907) that the specific gravity of chitin precipitated from its solution in strong acids approximates to the value of 1·398, and that its refractive index lies between 1·550 and 1·557. In the present case the refractive index agrees with the figure given by Sollas, but the specific gravity is somewhat lower, which may perhaps be due to the concentric formation of the object and its apparent porosity to air and water.

Apart from its lower specific gravity, the present 'pearl' differs from that examined by Herrick in one or two very important respects. The previous specimen had a flat end, which, according to Herrick, represented its place of attachment with the outer shell; the present 'pearl' does not show any signs of ever having been attached. The latter is also formed of close concentric layers, while Herrick's specimen was apparently one homogeneous mass. Further, the surface of the 'pearl' examined by Herrick was punctate, the punctations, according to Herrick, representing the 'hair-pores' of the crustacean shell; in my specimen there are only very fine close striations on the surface.

It is very difficult to express any definite opinion about the origin of this curious object. Herrick was of the opinion that it must have been formed by an ingrowth or pocketing of the outer shell due to some mechanical injury, probably soon after a moult. As

a connexion would be retained with the outer shell, this would involve the shedding of the 'pearl' at the next moult, and unless the irregularity of growth is obliterated, similar structures would be formed and shed at subsequent moults. The present specimen, however, does not show any point where it could have been attached to the shell. Further, the apparently concentric nature of its formation suggests that layer after layer of chitin has been added at each moult. It seems possible, therefore, that some cells of chitin-producing epithelium may have got pushed into the mesoderm, probably due to some injury when the skin was soft; and the connexion with the outer shell being cut off, the cells went on producing chitin, and, according to their function in normal conditions, went on adding layers at subsequent moults. There is still another, though remote, possibility. It is conceivable that some of the mesodermal cells themselves, as a result of some peculiar, unknown stimulus, have taken on the function of the chitinogenous epithelial cells. Differentiation and dedifferentiation of tissues is known to occur at the time of regeneration, metamorphosis, and similar phenomena. Perhaps something similar has happened in this case also.

My best thanks are due to Dr. J. A. Dunn for all the help he has so kindly given me.

Eugenic Sterilisation.

As a member of the Committee of the Eugenics Society for Legalising Eugenic Sterilisation, I should like to be allowed to say a few words concerning the leading article in Nature of Aug. 30 on our proposals. It is stated there: "Is there not a real danger that the advocates of such legislation as here may mistake the assent of the political machine for victory? If assent were gained, would it not be much more accurately determined as the hall-mark of failure? It is not the assent of the State, but the initiative and creative power of the State, that is needed to secure essential progress. . . ."

With the last sentence I entirely agree; but I fail to perceive how a step in the right direction can be regarded as the hall-mark of failure—unless, indeed, the Committee should be so stupid as to believe that the taking of this one step had brought us to our final goal, which is certainly not the case. The article opens with references to the difficulties in the way of progress which are created by timid and ignorant public opinion, and continues, "if, as Sir Walter Fletcher has lately pointed out, a mere ailment, like cancer, has only been made accessible to scientific study through the lifting of foolish and superstitious taboos, how can we expect the direr social maladies to be approached courageously?" I think I can speak for the Committee in saying that we realise to the full the extent of these intangible difficulties, and that it is precisely for that reason that we have concentrated on a small but tangible and urgent beginning. Somehow or other the public has to be made race-conscious, has to be imbued with the eugenic idea as a basic political and ethical ideal. We believe that a campaign of the kind we have launched, directing attention to a gross racial defect, will be the best possible way of turning their thoughts in the desired direction.

Comment is also made on the fact that the prevention of reproduction by all defectives would only lower the incidence of mental defect by about 17 per cent in one generation. The article fails to remind readers that the process is cumulative, and also does not point to any other way in which it could be reduced more rapidly. Finally, the most relevant fact of all is omitted, namely, that one of the greatest obstacles to securing assent to the sterilisation of defectives has been and is the widespread belief that, since two normal persons may have a defective child, therefore preventing defectives from reproducing will have no effect on the proportion of defectives in later generations. Dr. R. A. Fisher has gone carefully into the matter, and has shown that, even when the most unfavourable assumptions are made, prevention of reproduction by all defectives would result in a reduction of some 17 per cent—which to me at least seems considerable, as it would mean that there would be above 50,000 less defectives in Great Britain after the lapse of the, biologically speaking, trivial span of one generation.

I am glad that Nature has directed attention to the gravity of the problem, and look forward with interest to further discussion of the problem in its columns.

J. S. Huxley.

King's College, London, W.C.2.

Prof. Huxley's letter leaves some doubt as to whether he is really in any fundamental disagreement with the article to which he refers. If he is, it is over the use made by the Committee of Dr. Fisher's calculation. Further discussion: yes, by all means. Only, it is rather inconvenient to have to keep an eye upon changing terms. The minimum reduction of the incidence of defectiveness of 17 per cent in a generation promised by Dr. Fisher is conditional upon the prevention of *all primary aments* from breeding. It was the contention of the article that the Committee's measure did not provide for the satisfaction of this condition. Prof. Huxley, like the Committee and the signatories to the letter to the *Lancet*, ignores this condition. In the last paragraph but one of his letter, Prof. Huxley says: "Dr. R. A. Fisher . . . has shown that, even when the most unfavourable assumptions are made, prevention of reproduction by all defectives would result . . ." The reader is left to assume that the "small but tangible and urgent" beginning would lead to this result, whether a 17 per cent decrease or more.

If the voluntary principle, emphasised so strongly by the Committee, is to operate, the fertility of "all living mental defectives" will not be prevented, and that is the condition underlying Dr. Fisher's calculation. Experience of the ways of the relatives of defectives and the insane would lead most people to the conviction that they are far from tractable. Ascertainment, again, the basis of the English figures, shows an amplitude of variation that suggests very serious differences in the efficiency of investigators or in the sense of responsibility of elected persons. In such matters the Committee aims at improvement.

It was certainly not intended to suggest that the Committee is stupid. The criticism is directed towards the machine it is trying to use. While the political wedge is often held to possess the same properties as its mechanical prototype, its thin edge seems at times to acquire graft-like properties which inhibit rather than facilitate further progress.

If the eugenic problem were only a biological problem, a generation would be, of course, a trivial span. It is often held to be a social problem as well, a problem created by man in the very short time that he has been occupied in making it possible for several men to live where one lived before. If that is true, should correctives be allowed to lag?

The present state of the law is so absurd that one would think the self-respect of legislators would secure its alteration.

The Writer of the Article.

Microphotometric Analysis of Movietone Sound Records.

IN a letter published in a recent number of NATURE (July 19, p. 93), Dr. Louis V. King announced a method of microphotometric analysis of movietone sound records. Evidently Dr. King has overlooked that this method was described by me seven years ago in a paper, "Photographic Recording and Photoelectric Reproduction of Sound", published in the *Transactions of the Society of Motion Picture Engineers*, No. 16, 1923. On page 113 of the paper, Fig. 24 serves to illustrate this method of sound analysis. A comparative study of analysis of sound records by means of Moll's thermoelectric microphotometer and Koch's photoelectric microphotometer was made in 1927. A brief report thereof was published in the *Bulletin of the American Physical Society*, vol. 4, p. 2, April 1929, and also in the *Physical Review*, vol. 33, p. 1094, 1929, under the title "Application of Microphotometers for the Analysis of Photographic Sound Records".

J. T. TYKOCINER.

Electrical Engineering Laboratory,
University of Illinois,
Urbana, Illinois, U.S.A., Aug. 16.

I AM greatly interested in Prof. J. T. Tykociner's comment on my short letter to NATURE on the microphotometric analysis of movietone sound records. Had I known of his work on the subject, I should certainly have referred to it. In view of some fog-alarm tests I was planning at the time, the purpose of the letter was to bring out any work which might have been done along these lines, as well as to direct the attention of lighthouse engineers to the extremely convenient method of recording the performances of fog-alarm installations afforded by the use of the movietone camera. I do not believe, however, that the records would have their full value without the use of a standard of sound of some kind, and I directed attention to this in view of the possibility of having some firm of instrument makers take up the design I had in mind, should there be a sufficient demand for this method of sound measurement. It should be possible, on the basis of Prof. Tykociner's researches, to have available for general use portable and easily operated instruments for recording and measuring sound.

LOUIS V. KING.

Metis Beach, Que., Sept. 14.

A Galvanometric Method of Measuring Electrolytic Resistance.

THE ordinary laboratory bridge method of measuring electrolytic resistance employing a telephone is somewhat unsatisfactory, owing to the difficulty of accurately judging the position for minimum sound in the telephones. Experiments made by different observers are, for this reason, often liable to give results which vary considerably. A method in which the telephone is replaced by a galvanometer possesses, therefore, a decided advantage, and the following simple device, which I have not seen described elsewhere, has been found quite satisfactory for ordinary purposes.

The points P and Q of the bridge (Fig. 1) are connected through a thermionic valve (Mullard type PM. 5) to a galvanometer. The grid and anode of the valve are joined, so that it constitutes a diode. An alternating potential difference between P and Q produces a unidirectional current through the galvanometer, since the diode acts as a 'half wave-rectifier'. The resistances in the arms of the bridge are adjusted until the galvanometer indicates zero, calculation being made in the usual way.

Owing to the high impedance of the valve, a sensitive galvanometer is required. Using a 'Pye Unipivot' instrument, of sensitivity about 2 divisions per micro-ampere, with resistances of 100 ohms in the bridge arms, and an applied potential of 30 volts, a change in resistance of 1 ohm in any of the four arms

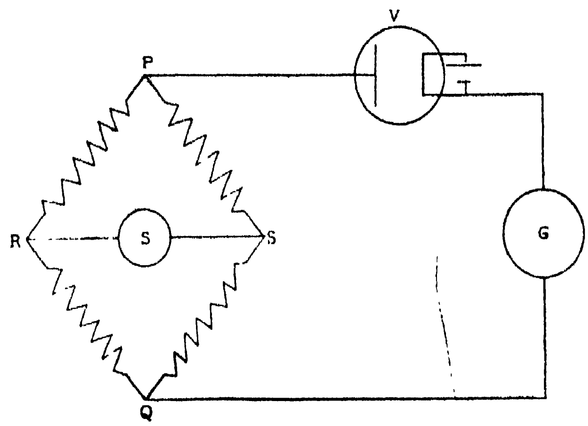

FIG. 1.

of the bridge produces an out of balance deflection of 2 divisions. For higher sensitivity a more sensitive galvanometer is required, but in such cases a very steady source of supply is essential. Obviously the deflection of the galvanometer is always in the same direction for all out of balance conditions, and does not pass from a positive value through zero to a negative value, as when the bridge is supplied with direct current.

Other methods of employing the thermionic valve in connexion with bridge determinations of electrolytic, and of very high wire resistance, in which use is made of the amplifying and rectifying properties of the valve, are to be published later in the *Indian Journal of Physics*.

Wireless Reflections and Echoes.

A REMARK has just occurred to the writer, on turning over the account of cognate phenomena in Rayleigh's "Theory of Sound" (vol. 2, § 270), which seems to be of weight in this subject and may indeed be already familiar as a guide to observers. Long waves can penetrate a heterogeneous atmosphere of the lumpy type much better than shorter waves the length of which is comparable with the dimensions of the patches scattered through the medium. But in reflection from a layer of transition the opposite conditions prevail, the longer waves being most turned back: for reflection is only sensible when the gradual change of properties is completed within a depth small compared with the wave-length, though the new values must afterwards be maintained for a depth at least comparable with the wave-length. Atmospheric reflection downward must be in any case slight so that the augmenting of the effect by lengthening the waves may be an effective mode of test.

JOSEPH LARMOR.

Cambridge, Sept. 3.

Veterinary Science and Agriculture.*

By Dr. P. J. Du Toit.

THE prominent position which veterinary research occupies in the scientific life of South Africa to-day and the valuable practical results which have been obtained in this field of work have encouraged me to choose as the subject of my address the rôle which veterinary science plays in the agricultural development of a country. For obvious reasons my remarks will be confined almost exclusively to the live-stock side of agriculture in the wider sense; and for equally obvious reasons most of my examples will be quoted from South Africa.

Since the beginning of the present century the growth of veterinary science has been remarkable. Indeed, it may be said that a new veterinary science has arisen unobserved by the general public. A quarter of a century ago the veterinarian was looked upon as a moderately useful though obscure member of the community, whereas to-day he is regarded as an essential factor in the economic machine of the State. In this transformation of veterinary science the British Dominions and Colonies played no unimportant part. The veterinarians who had migrated to those countries and taken with them the stock of knowledge which they had obtained at the European veterinary schools, found themselves confronted with new problems which required solution. Research work on a large scale became necessary. Novel methods of attacking disease had to be devised. The farmer soon came to realise that his very existence depended on the protective measures of the veterinary staffs.

I propose to review briefly some of the most notable achievements of veterinary science in recent years, and to indicate how the work of the veterinarian has become interrelated with that of workers in other branches of science.

Animal Diseases.

Trypanosomiases.—Probably no other single group of disease-producing organisms has retarded the agricultural development of the continent of Africa more than that of the trypanosomes. If the cattle population of Africa be estimated at about 40 million head, it is quite safe to say that this number could easily be doubled if the danger of trypanosome infection were removed. In Nigeria, for example, only a portion of the drier northern provinces is suitable for cattle ranching; the much more fertile southern provinces are practically devoid of cattle on account of the ravages of trypanosomiasis. Similar conditions obtain in almost every territory in Africa (except the extreme south). The soil is fertile, grazing is plentiful, the climatic conditions are favourable, but the presence of tsetse flies and trypanosomes renders cattle farming impossible.

Fortunately, we can record considerable progress in this field of work during recent years. The problem has been attacked along two lines mainly. A direct attack has been launched against the parasite by means of drug treatment; and an indirect attack on the disease has been made through a campaign against the transmitter, the tsetse fly. The third line of attack, the immunisation of animals against infection, has not yielded very promising results.

One further trypanosome disease should be mentioned here, namely, dourine. Known for about a hundred and fifty years, this disease has been responsible for very heavy economic losses to horse breeders in Europe and other countries. With the aid of modern methods the disease was eradicated from most of the closely settled and well-organised western European States. But in the vast open spaces of Canada and other countries its eradication proved to be a much more difficult problem. It was only when Watson in Canada succeeded in perfecting a delicate diagnostic test for the detection of the infection that the eradication of the disease could be attempted seriously, and the results of the subsequent campaign in Canada have been entirely satisfactory. It should be added that Watson's success has stimulated further research into the problem of diagnosing other trypanosome infections by serological methods. A fair amount of success has attended these efforts and quite recently Robinson at Onderstepoort has reported further progress in the serological diagnosis of *Trypanosoma congolense* infection.

Piroplasmoses.—Under this heading are included diseases like redwater or Texas fever of cattle, biliary fever of dogs and horses, 'gallsickness' or anaplasmosis, and East Coast fever of cattle.

Their etiology was completely obscure until Theobald Smith and Kilborne in America, in a series of brilliant researches extending over the years 1888–92, succeeded in elucidating the nature of the first-named disease. Not only did these investigators discover the causal organism in the blood of infected cattle, but they also proved that the disease was transmitted by ticks and that the infection passed through the egg of the tick from one generation to the next. All this was completely new to science; it was the first time that the transmission of a mammalian disease through an invertebrate host had been proved experimentally. This contribution to science by two veterinarians is worthy of special note.

In the case of redwater, great advances can be recorded. The direct method of attack is eminently satisfactory, thanks to the discovery by Nuttall and Hadwen in 1909 that the drug trypanblue has a specific action on the parasite of redwater of cattle and biliary fever of dogs. The treatment is so successful that the disease has lost much of its terror since the discovery of the value of this drug.

In the case of anaplasmosis, a method of immunisation has been practised in South Africa for nearly twenty years and has been the means of saving thousands of animals.

Of the diseases mentioned in this section, East

* From the presidential address to Section M (Agriculture) of the British Association, delivered at Bristol on Sept. 8.

Coast fever is the most formidable, because of the very high mortality attending it. This disease must have cost South Africa several million pounds since its first appearance nearly thirty years ago. The loss to the country has been partly direct through the death of many thousands of animals, partly indirect through the costly organisation which it is necessary to maintain to fight the disease.

It is impossible in this brief review to discuss the methods employed in the eradication of East Coast fever, or the many practical difficulties encountered in this campaign. For our purpose it is sufficient to state that the dipping of cattle in an arsenical bath has proved to be a very valuable aid in the fight against East Coast fever or any other tick-borne disease.

In South Africa dipping has been practised since the beginning of this century, and has now become an integral portion of the daily routine of farming. No up-to-date stock farm can be found to-day without at least one dipping tank. Even if all the tick-borne diseases should now disappear, the majority of farmers in South Africa would continue to dip their animals regularly. The extent to which dipping is practised to-day may be gauged by the fact that there were in the Union of South Africa in 1929 more than 13,500 dipping tanks.

In the United States of America, where Texas fever (redwater) is the only serious tick-borne disease, an attempt is being made to eradicate completely the transmitter, *Boophilus annulatus*, by means of dipping. Large areas have already been cleared of these ticks, and the economic advantages to which these areas are entitled after being declared tick free, more than compensate for the expenses incurred.

Virus Diseases.—The vast sums of money which have been spent in Great Britain during the last few years on the eradication of foot-and-mouth disease should convince even the layman of the importance of this group of diseases.

In the olden days it was rinderpest which caused the severest losses. It has been calculated that the losses in Europe during the eighteenth century amounted to 200 million head of cattle. The disease made its appearance in England in 1865. A Royal Commission was appointed and its report is of value to this day. Later on, improved methods of eradication and prevention were evolved, and to-day most countries are free of rinderpest. However, in the Far East and in Central Africa the disease is still prevalent, and causes serious losses.

Two recent outbreaks of rinderpest, one in Belgium in 1920 and the other in Australia in 1923, both of which were eradicated completely within a few months, have again shown how far veterinary science has advanced during the last century.

South Africa has been free of the two diseases just named for many years. But there are several other virus diseases which play a very important rôle. Among these, horsesickness and bluetongue of sheep are perhaps the most important. An extensive study of the former disease by Theiler and his co-workers has yielded some very valuable results, but the problem of horsesickness cannot be said to be solved. At present a method of immunisation with hyperimmune serum and virus is practised, and this method has given excellent results in mules. About 4000 mules are immunised annually, and it has been stated that if the Onderstepoort Laboratory had produced nothing else except this method of immunising mules, its existence would have been justified.

The second important virus disease of South Africa is bluetongue of sheep. The disease is of great economic importance and would have been a very serious hindrance to the sheep farmer had it not been for the fact that Theiler discovered a simple method of vaccination by means of which the losses from the disease can be reduced to a negligible quantity. Every year two to three million doses of this vaccine are issued to the farmers, and the ultimate saving to the country must be enormous.

Of the many other virus diseases of animals, only one more need be referred to here, namely, rabies. This most dreaded of all human and animal diseases has been eradicated from many countries, and is being kept out by strict quarantine measures. In 1918 the disease was introduced into England with a dog which had been smuggled in in an aeroplane. Strict measures were put into force and in a comparatively short space of time the disease was stamped out completely. Methods of preventive inoculation of dogs, in countries where the eradication of the disease is very difficult, have been tried on a large scale. The results have, on the whole, been very good; but it is too early to predict the future scope of these methods.

Bacterial Diseases.—Of the host of bacterial diseases, only a few need be mentioned here. The deadly glanders, which was known before the time of Christ, and even twenty-five years ago still caused severe losses amongst horses and constantly threatened the human population, has now been practically eradicated from all civilised countries—thanks to the accuracy of the diagnostic tests which are used to identify the disease.

Another disease which at one time was responsible for very serious losses and which has now practically disappeared is pleuro-pneumonia (lungsickness) of cattle. In the year 1860 about 187,000 head of cattle are stated to have died in Great Britain of this disease; and the mortality in other European countries at that time was corresponding high. Towards the end of last century the disease was stamped out in Britain and to-day the greater part of Europe is free of the disease. South Africa, in spite of the fact that neighbouring countries are still infected, has been free of lungsickness since 1915.

Only one other bacterial disease can be mentioned here, namely, tuberculosis. In 1901, Robert Koch, who about twenty years previously had discovered the cause of the disease, startled the scientific world by announcing to a Tuberculosis Congress in London that human tuberculosis and bovine tuberculosis were two distinct diseases which were not communicable from the one species to the other. Unfortunately, this statement proved to be wrong. We know to-day that human beings do contract bovine tuberculosis, and for this reason most

civilised countries adopt measures for the suppression of the disease in cattle. The United States and Canada are leading the world in this respect and have spent millions of pounds in compensation for the destruction of tuberculous reactors. Denmark, Germany, England, and other countries are also doing much and have achieved a large measure of success in their efforts to supply to the population milk and beef free of tubercle bacilli. But very much remains to be done. In human beings the mortality from tuberculosis is still high in all countries, and a considerable percentage of the deaths must be ascribed to the bovine strain of the organism. The disease in cattle *can* be stamped out provided enough money is made available.

Recently great interest has been shown in the attenuated strain of tubercle bacilli produced by Calmette and Guerin of the Pasteur Institute. Experiments in which it is attempted to immunise children and young animals, with this strain, are in progress throughout the world. It is sincerely hoped that all this work will prove that the method of Calmette and Guerin has given us yet another weapon against this insidious disease.

Internal Metazoan Parasites.—The only group that need be mentioned in this brief survey are the worms. These parasites have become more and more important and to-day they actually constitute the 'limiting factor' in successful sheep farming in many parts of the world. This subject forms a highly specialised science of its own, the science of helminthology—in which many notable successes have been achieved in recent years.

The ordinary stomach worm of sheep (*Hæmonchus contortus*) is world-wide in its distribution and is the cause of very severe losses. Better farming methods will undoubtedly improve the position, but in the meantime farmers look to the veterinarian to rid their sheep of these deadly parasites. Various chemicals have been tried with varying degrees of success, but perhaps nowhere has the success been so marked as in South Africa, where, as a result of the researches of Theiler, Veglia, Green, and others, a method of treatment was recommended which has proved the salvation of many sheep farmers. The method consists of the accurate dosage of a mixture of arsenite of soda and copper sulphate; and the extent to which this method has been applied may be gauged from the fact that at present some 25 million doses of the mixture are issued annually from Onderstepoort. The method is not perfect, but it has been a great factor in making sheep farming a success where otherwise it would have been a dismal failure.

One further fact must be emphasised here. The menace of worm infection has become so great that no sheep farmer can hope to be successful if he disregards the teaching of modern science. Overstocking of farms must be prevented at all costs; marshes must be drained or the sheep kept away from them; the sheep must be treated regularly according to the best methods known. If these precautions are adopted, the parasites can be kept in check and profitable sheep farming will become possible; if the advice is ignored, then the financial loss to the farmer will be the smaller the sooner he gives up farming.

External Parasites.—The two most important groups of ecto-parasites, the ticks and the tsetse flies, have already been referred to.

A further very important group are the mites. These minute parasites are responsible for the diseases known as scab or mange in animals, and have caused untold losses. In the fight against these diseases the British Dominions have had very signal success. Australia and New Zealand have eradicated sheep scab completely, Canada is practically free of it, and in South Africa, where the presence of a large native population owning a very inferior class of sheep has made the campaign particularly difficult, the incidence of the disease has been reduced to infinitesimal proportions and complete eradication is hoped for within a short time.

Another very important ecto-parasite of sheep is the so-called blowfly. The trouble is caused by these flies depositing their eggs in the wool of sheep, especially in the soiled and moist parts, and by the resulting maggots causing serious damage to the wool and the sheep itself. The pest has assumed alarming proportions in Australia and is becoming more and more important in other countries, including South Africa. Determined efforts are being made to combat the pest and valuable progress has been achieved. In this research entomologists and veterinarians are working hand in hand.

Diseases due to Poisonous Plants.—That certain plants are poisonous and may have fatal effects when consumed by animals has probably been known for centuries. However, it is only during recent years that plants have been studied which produce diseases comparable with epizootic diseases. In this field of research South African workers have been prominent.

One of the most remarkable of these diseases is that known in South Africa as gousiekte (rapid disease) of sheep, which was studied some years ago by Thieler, Du Toit, and Mitchell. The cause of the disease was shown to be the plant *Vangueria pygmæa*. The poison contained in the plant acts on the heart muscle, causing a myocarditis with subsequent dilatation of the ventricles. As soon as the process has reached a certain stage the animal dies of 'heart failure'. To the casual observer the disease presents all the characteristics of an infectious disease.

Other no less remarkable diseases were studied by Theiler and his co-workers. A disease called geeldikkop (yellow thick head) in sheep was shown by Theiler (1928) to be due to a plant *Tribulus terrestris*, although more recent work by Quin, Steyn, and others at Onderstepoort has shown that there are other factors to be considered in the causation of this disease.

Vomiting disease of sheep was studied by Du Toit (1928) and proved to be caused by *Geigeria* spp. The disease may produce very severe losses in certain years, especially after droughts, when the plant is very widespread.

The study of poisonous plants is now being actively pursued in various countries, and further

interesting developments may be expected. It is obvious that the co-operation of botanists is essential for the success of this work.

Deficiency Diseases.—The great importance of the vitamins in the nutrition of human beings is so well known that it need not be stressed here. In the case of the common domestic animals (except perhaps the pig, the dog, and the fowl) the vitamins seem to be of far less importance than in human beings. On the other hand, mineral deficiencies are, generally speaking, much more important in animals than in human beings. In recent years it has been found that large portions of the earth's surface are deficient in some mineral or other essential for the normal health and growth of animals.

In South Africa, as well as in other African territories and in Australia, the most serious deficiency is that of phosphorus. Theiler and his co-workers have investigated the ill-effects of this deficiency on cattle very fully. They have shown that cattle grazing on phosphorus-deficient pastures develop a depraved appetite for bones and other carcase debris, and this may lead to the ingestion of toxic material with fatal results (lamsiekte in South Africa); further, that such cattle remain stunted in growth, are late in maturing, are frequently unfertile, produce very little milk, and are very susceptible to various diseases. By the addition of a small daily ration of phosphorus to the diet, they were able to bring about an almost miraculous improvement in the condition of the animals.

As a result of the general feeding of phosphorus compounds in the deficient areas of South Africa, the disease lamsiekte, which a dozen years ago caused enormous losses, has practically disappeared and cattle farming in those areas has again become profitable. The significant fact may be recorded here that the village of Vryburg in Bechuanaland, where ten years ago milk was very scarce, to-day owns a creamery which handles a larger volume of cream than any other creamery in South Africa.

Other Veterinary Problems.

Problems in connexion with the nutrition of animals are now receiving attention in many countries. The vast importance of correct feeding can be illustrated best by referring again to the phosphorus deficiency which exists in the pastures of South Africa and other countries. The astounding results which have been achieved with the addition of a small quantity of phosphorus compounds to the ration of the animals promise to revolutionise the beef and dairy industries.

Animal breeding also presents problems of great importance and these are intimately bound up with the problems of disease and nutrition. In South Africa, as in other countries, there is a constant cry for the replacement of the scrub bull by pedigree sires. This demand would be met to a far greater extent were it not for the fact that in many parts of the country pedigree bulls cannot live because of disease or nutritional difficulties.

In South Africa control over the diseases mentioned above is gradually improving and, in regard to the deficient areas, recent investigations by Du Toit and Bisschop have shown that the grading up of native stock can be carried out with complete success provided the deficient mineral is supplied. Both beef cattle and dairy cattle have been bred on the extremely deficient veld of Bechuanaland without signs of deterioration, and the cost of the supplementary ration has been negligible in comparison with the advantage derived from such feeding.

Gratifying though the success which has been achieved may be, the need for further research on live-stock problems has never been greater than it is to-day. The development of enormous areas in the British Dominions and Colonies is entirely dependent on the progress of research. With the aid of further scientific measures, these new countries could absorb a very much larger population than they now harbour. Over-population will not make itself felt for generations, nor need over-production be contemplated seriously.

The prosperity of a very large percentage of the population, both European and native, in the Dominions and Colonies depends on the live stock industry—breeding of pedigree stock; beef, mutton, or pork production; dairy farming; wool or mohair production; skin and hide trade; poultry farming, etc. These farmers look to the veterinary service of their countries more and more for assistance and protection. Without this assistance, profitable stock farming, especially in the tropical and subtropical countries, is impossible. The assistance, if it is to be effective, must be based on the latest achievements of scientific research. Rule-of-thumb methods will not suffice.

In a humble way South Africa has proved the wisdom of maintaining an adequate veterinary research service. At Onderstepoort the Government twenty-one years ago established what must be regarded as a fairly large research institute, if the size of the population be taken into consideration. This institute, under the brilliant directorship of Sir Arnold Theiler, soon proved to be not a liability but a valuable asset to the country. The results obtained in any one of its various sections would probably have justified the maintenance of the entire institution.

I have said that the Dominions and Colonies have played an important part in the recent growth and development of modern veterinary science. The quality of the research work produced by veterinarians in these countries has been of such high order that it soon placed veterinary science (which not many years ago was regarded as the Cinderella of sciences) abreast of the other sciences. As a matter of fact, in South Africa it can be said, without disparagement to any other group of workers, that veterinary science occupies a very high, if not the leading, position. This has had a wholesome influence on the science itself and on the type of worker who was recruited in its service. The stigma of inferiority which for so long was attached to the veterinarian has disappeared. To-day, veterinary science is looked upon as a field of work which offers almost unlimited scope for research and, in its practical application, may bring untold material benefit to a country.

Correlation of the Archæological and Geological Records.

By M. C. BURKITT.

FOR the prehistorian the problem of correlating the archæological and geological records is a thankless task. No sooner has a satisfactory correlation been obtained in the study than field workers produce fresh factors which have to be accounted for and the problem is demonstrated to be still more complicated than before. However, recent researches, especially those undertaken by Mr. Reid Moir and Dr. K. S. Sandford, have thrown a flood of light on the whole matter, and while it is still too early to hope for a final solution of the knotty problem, a comparison of their work with that of earlier continental investigators does bring out certain salient points.

Although it has undergone some vicissitudes, the fourfold glacial system of Penck certainly seems to meet the facts in Nature, although the length and the intensity of the glaciations of that scheme seem to have differed in various areas, not only according to latitude (as might be expected) but also according to the longitude of the site. However, for the purpose of this article, Penck's scheme will be adopted, not least because both Mr. Reid Moir and Dr. Sandford, as well as many continental prehistorians, have a fourfold glacial system in their minds. Before tabulating the recent work in East Anglia and the Oxford district, it will be well to summarise some of the results obtained abroad: chiefly must the results of investigations at three sites, namely, Bouchiéta, Conliège, and Cotencher, be combined together.

Bouchiéta.—This site is a small cave half-way up the steep side of the Soudour hill, which rises in the middle of a tributary valley of the Ariège, close to the village of Bedeilhac and not far from Tarascon-en-Ariège. The section in the cave revealed morainic material overlaid by a deposit containing Mousterian implements. Below the level of the cave, along the hillside, can be seen the remains of another lateral moraine due to a glaciation which was not sufficiently intense to rise to the height of Bouchiéta. This glaciation must, of course, have been subsequent to the one which did reach the cave, as its moraines have not been thereby obliterated. If it *had* been sufficiently intense to reach the cave, doubtless the contents would have been cleaned out, and the remains left by the previous glaciation, with the deposit containing Mousterian implements resting on it, largely destroyed. *The evidence at Bouchiéta thus demonstrates that some Mousterian industries are subsequent to a glaciation which was not the last.*

Conliège.—In eastern France two terminal moraines can be determined, one considerably farther out in the plains than the other, due of course to the fact that the glaciation which formed it was the more intense of the two. But that the greater glaciation was not subsequent to the lesser is obvious, because if it had been, the terminal moraine of the former would have been largely destroyed. In a deposit resting on the earlier moraine, that is, the one farthest out in the plains, and beyond the range of the subsequent and lesser glaciation, was found an Acheulean implement. It is hard to dogmatise about the exact age of a single specimen, but so far as can be judged from pictures, it does not seem to be of very early Acheulean date. *The evidence at Conliège demonstrates that a part at any rate of the Acheulean culture is subsequent to the last but one important glaciation of a district.*

Cotencher.—This site is in Switzerland (Neufchâtel). It is a small cave lying just within the orbit attained by Penck's Würm glaciation at its maximum, and it was completely filled by morainic material assignable to this last great glacial epoch. Within the morainic material were found some Mousterian tools, which must therefore have been fashioned and dropped before the Würm glaciers picked them up and deposited them at Cotencher. *Cotencher demonstrates that the Mousterian culture, in part at least, was anterior to the maximum of the Würm glaciation.*

But the Mousterian in France * is found with an arctic fauna and is stratigraphically later than the Acheulean, which is associated with a cool fauna. It follows, therefore, that the French Mousterian must be, in part at any rate, correlated with the Würm glaciation, it and a part at least of the Acheulean being subsequent to the Riss glacial period. Confirmation of this is given by the finds in the Somme Valley, where Acheulean industries occur in the older loess, which is found covering, and is therefore newer than, the lowest but one terrace, while it never overlies the bottom terrace—for the simple reason that at the time of its formation the bottom terrace was not there. Mousterian industries are found at the base of the younger loess, which does occur over the bottom terrace as well as over the lowest but one. Comparisons of the Somme Valley terraces with those of the Oxford district are very striking. Again, in the valley of the Garonne, Acheulean industries are found in a deposit resting on the lowest but one terrace and in the gravels of the bottom terrace—in the latter case in a rolled state. Once again the evidence shows that a part at any rate of the Acheulean industries can be dated to a period before the last glaciation but after the last but one.

Turning to Great Britain, the key sites in East Anglia are, in my opinion, those of Hoxne and the Cromer cliffs, to which must be added the recent discoveries in brown boulder clay at Hunstanton. Our knowledge of all three is due to the indefatigable energy of Mr. Reid Moir. Composite sections from

* I use the terms 'Mousterian in France' and 'French Mousterian' to distinguish these industries from the many flake industries found elsewhere, for example, in Great Britain, which have often been erroneously classed as Mousterian but are better designated 'Levalloisian' or 'Clactonian', and are often considerably earlier in date, being contemporary with various phases of the Acheulean culture.

these sites, together with those of the Oxford district, are given in the table below. The archæological finds from the Wolvercote channel have been correlated with the upper beds of Hoxne, the succession of industries being most helpful. The foreign evidence just detailed allows us to name the glacial periods according to the Penckian scheme. sands with the more temperate beds, probably lower Acheulean in date, of Hoxne and elsewhere. But the recent suggestions of Simpson (NATURE, Dec. 28, 1929) postulate a cold or at least cool inter-glacial at just about that time in the geological sequence of events. Assuming that the climate was temperate, as indicated by the Hanborough

TABLE OF CORRELATIONS.

Locality.	Oxford Region.		Hoxne.	Hunstanton.	Travellers' Rest, Cambridge.
Post Würm I	Modern flood plain gravels.		Sand and sandy-loam (? Upper Palæolithic in age).	Brown boulder clay containing derived Upper Palæolithic implements = Würm II.	Evenly bedded gravel at top.
Glacial Times = Würm I	Sunk channel (mammoth found). Denudation to sunk channel.	[Wolvercote channel] 1. Warp sands (climate very cold and wet). 2. Clays with rare Mousterian tools (climate cold). 3. Peats with subarctic flora.	[No industries found but presumably they would prove to be late Mousterian and early Upper Palæolithic.] Glacial deposits = chalky boulder clay. Brick earth.		Twisted loam and sand.
Interglacial Times = Riss-Würm	Upper Summertown–Radley terrace. (Hippo and *Corbricula flummalis* found.)	4. Sands with temperate Mollusca. 5. Layer with *Elephas antiquus* and unrolled Upper Acheulean and Micoque tools.	Early 'warm' Mousterian floor and temperate flora.	[Cromer District.]	Twisted sand (Moust.). Warm level-bedded sand (derived Chellean and Acheulean tools).
Glacial Times = Riss	Lower Summertown–Radley terrace. (Mammoth and derived Chellean and Acheulean tools found.) Wolvercote (40 ft.) terrace = outwash of Moreton ice sheet (derived Chellean tools found).		Gravel with Acheulean tools mammoth and reindeer bones. Arctic bed (sterile).	Runton sands (Upper Acheulean tools found). Contorted drift.	Scratched boulders.
Interglacial Times = Mindel-Riss	Hanborough (90-100 ft.) terrace pause in a period of denudation of the Thames valley.		Warm lacustrine beds (sterile).	? Perhaps represented by such a deposit as the Mundesley sands.	
Glacial Times = Mindel	Plateau drift.		Kimmeridge boulder clay.	Till (derived late Chellean tools found at base). Upper part of Cromer Forest Series.	
Interglacial Times = Günz-Mindel				Lower Cromer Forest Series. (Horizon of ancient Chellean land surface at base.)	
Glacial Times = Günz				Weybourne Crag, etc.	
Pre-Günz Times				Earlier Pliocene deposits to chalk.	

It would seem from the above that the whole period from the Eolithic industries of the sub-crag until close on chalky boulder clay times is occupied by Chellean and Acheulean industries, with which are associated at certain periods flake industries of Clactonian and Levalloisian types. The so-called 'warm' Mousterian which is earlier in date than the true Mousterian of France should, properly speaking, be included here. The only difficulty in the scheme is the correlation of the cold Mundesley terrace at Oxford and the lower bed at Hoxne, it is possible that in the intensely glaciated area around Cromer, which was more or less under the influence of the Scandinavian ice-sheets, the climate of this cool inter-glacial period was never warm enough to permit of our recognising an inter-glaciation, but that nevertheless the Cromer Till and the contorted Drift, far from being the result of one great glacial movement, are the result of two successive glaciations.

Obituary.

PROF. H. B. DIXON, C.B.E., F.R.S.

THE sudden death of Prof. Harold Baily Dixon, of the University of Manchester, on Sept. 18 last, removed a distinguished chemist whose work upon gaseous explosions during the past half-century opened a new era in combustion research.

He was born on Aug. 11, 1852, the second son of William Hepworth Dixon (1821–79), traveller and writer, and for some years (1853–69) editor of the *Athenæum*. The family came of an old puritan stock, the Dixons of Heaton Royds in Lancashire; but in 1846 Hepworth Dixon, who had been born in Manchester, migrated to London, where his children were reared.

Harold went to Westminster School, from whence, in 1871, he gained a close classical scholarship at Christ Church, Oxford. Owing chiefly to the zest with which he threw himself into the social and athletic side of university life, he scarcely fulfilled the expectations of his tutors in classics; but in 1873, at the instance of Dr. A. Vernon Harcourt, he turned his attention to science, with such signal success that two years later he graduated first class in the Natural Science School. Afterwards he was elected to fellowships successively at Trinity in 1875, and at Balliol in 1881, teaching at both Colleges and carrying out researches in a cellar at Balliol which formerly had been used by Benjamin Brodie for his researches on ozone.

It was also at the instigation of Vernon Harcourt that Dixon commenced studying gaseous explosions in 1876. During the sixty years which had elapsed since Humphry Davy's pioneering work on the subject, only R. W. Bunsen amongst chemists had much explored it, and for twenty years his results had been accepted without question as authoritative. More particularly the results of Bunsen's experiments (1853) on the explosion of mixtures of electrolytic gas with increasing amounts of carbonic oxide were held to be inconsistent with the principle of 'mass action' enunciated by Berthollet in 1805, and led to the erroneous view that a continuous alteration in the composition of such a gaseous medium produces a discontinuous ('per saltum') alteration in the course and products of its explosion.

It was during a research primarily undertaken to test this conclusion that Dixon made the epoch-making discovery that the prolonged drying over phosphoric anhydride of a mixture of carbonic oxide and oxygen in combining proportions renders it non-explosive when subjected to electric sparks of an intensity sufficient to ignite quite readily an undried medium. This astounding result, announced at the Swansea meeting of the British Association just fifty years ago, immediately made him famous, and (as he was wont to say) loosed a hare which, though since pursued by the hounds in full cry, is still uncaptured.

These early Oxford researches (1876–81) not only proved, *contra* Bunsen, the validity of Berthollet's 'law of mass action' in gaseous explosions, a conclusion simultaneously established by the independent work of Horstman in Heidelberg, but also led to the remarkable discoveries of H. B. Baker, who assisted Dixon at Balliol in 1884–85, regarding the incombustibility of rigidly dried and purified systems containing phosphorus or sulphur vapour and oxygen, even when strongly heated. Thus Dixon laid a firm and lasting foundation on which much later work has been built.

Up to 1880, on the strength of Bunsen's observations (1857), it was generally believed that gaseous explosions travel at rates not exceeding a few metres per second only; but in that year a disastrous explosion in a large gas-main in Tottenham Court Road, London, afforded conclusive evidence of much higher speeds. and caused Dixon to begin measuring 'rates of explosion', which was his next important work. He had not got far with it, however, before Berthelot and Vieille announced (1880) their discovery of the high constant flame speeds finally attained on the development of 'l'onde explosive' ('detonation') in gaseous explosions; this revelation, together with Mallard and Le Chatelier's classical "Recherches sur la combustion des mélanges gaseux explosifs" (1883), showed that the comparatively slow flame speeds observed by Bunsen apply only to the mild initial phase of such explosions. Working on parallel lines with them during the next twenty years, Dixon so successfully developed the methods initiated by the French savants that he became the leading authority upon such matters. In 1893 he gave the Bakerian Lecture to the Royal Society on "The Rates of Explosion in Gases", and nine years later published in the *Philosophical Transactions* a brilliant memoir embodying his photographic researches on "The Movements of Flame in the Explosion of Gases".

Dixon's third principal line of research, which chiefly occupied him during the last twenty years, was on the 'ignition temperatures' of explosive gaseous media, which he was the first to determine with any real accuracy; and only recently he made the important discovery that such 'ignition temperatures' are, or may be, profoundly affected by the presence of small amounts of impurities in the media, a matter of great importance in regard to coal-mine and other industrial explosions.

In 1886 Dixon was appointed to succeed Sir Henry Roscoe in the chair of chemistry at Owens College, Manchester; and this he occupied until his retirement in 1922, when he became honorary professor at the University while still continuing his experimental researches there. Under Roscoe the Manchester School of Chemistry had been so dominant in the country that some doubted whether his successor would maintain its great reputation. But Dixon's outstanding administrative gifts, his devotion to experimental research, his singularly clear and penetrative mind, his brilliance as a lecturer, his power of arousing in his students the true spirit of inquiry, and the way in which he always identified himself with the social and athletic interests of the University,

proved more than equal to the test, so that the reputation of the School continually increased under his leadership. He was indeed the *beau ideal* of a University professor.

Dixon's scientific and educational activities were by no means confined to the University of Manchester. He was president of the Manchester Literary and Philosophical Society during 1907-9 and of the Chemical Society during 1909-11. He served on the Royal Commissions on Explosions of Coal-dust in Mines (1891-94) and on Coal Supplies (1902-5); also he was a member of the Home Office Executive Committee on Explosions in Mines (1911-14), and since 1927 acted as Supervisor of Researches on the Ignition of Gases under the Safety of Mines Research Board. During the War he was Deputy Inspector of High Explosives for the Manchester area, in recognition of which he was appointed C.B.E.

In 1916 Dixon became chairman of the Royal Technical College, Salford, and afterwards of the Salford Education Committee, both of which positions he continued to fill until the end with conspicuous success and great advantage to the public. Latterly he also devoted much time to the establishment of the new Queen Mary's Secondary School for girls at Lytham, which is to be opened in the near future, and was returning from a meeting at Lytham in this connexion when he was suddenly taken ill and died.

Amid his manifold other interests, Dixon never lost his early love of the classics, and while voyaging to South Africa with the British Association in 1906 he produced for private circulation a verse translation of the Odes of Horace which for scholarly treatment and real feeling could scarcely be surpassed. Indeed Horace and Omar Khayam were his favourite authors, and he was filled with the spirit of the "Novum Organon" of which his scientific work was the fruit.

The Royal Society elected Dixon to its fellowship in 1886, and awarded him a Royal Medal in 1913; in 1922 the University of Manchester conferred upon him its D.Sc. *honoris causa*, the University of Prague having similarly conferred its Ph.D. some years previously. But, as he often said, his chief reward was the deep satisfaction which came to him through the affection and devotion of his many old pupils, and from the knowledge that, inspired by his example, they were handing on the torch which he had lighted.

Dixon was not only himself a great exponent of the experimental method, but also a master-trainer of those who were privileged to be his pupils in research; and it was here that the influence of his personality was most markedly felt. At all times he was unsparing in the guidance of his ripe experience, and unrelaxing in impressing the paramount duty of accuracy and truth, together with the highest standard of experimental work. Eschewing all rash speculation, and attaching little importance to theories save as working hypotheses, the dry light of science shone clearly throughout all his work; and he had a singular felicity in choosing just the right words in expounding it.

In his youth, Dixon was a good athlete, gaining his football 'blue' at Oxford; and well into middle life he continued to play both cricket and tennis. His chief physical recreation, however, was mountaineering, in which he excelled. During 1890-93 he accomplished more than twenty first-class climbs in the Alps, and was elected to the Alpine Club in 1894. Afterwards, in 1897, he climbed in the Selkirks, Canada, making first ascents of both Pollux and the Dome, and the second ascent of Castor with C. E. Fay and others. Also, in the Canadian Rockies, he made the first ascents of Mounts Lefroy and Gordon with C. E. Fay, Norman Collie, and C. S. Thompson.

He was twice married, first in 1885 to Olive Beechey Hopkins of Montreal, who died in 1917, and by whom he had a son and a daughter; and then in 1918 to Muriel Kinch of Yelverton (S. Devon), who survives him, by whom he had a daughter. All three of his children also survive him.

It is pleasing to know that even on the last morning of his life, Dixon was personally experimenting in his laboratory; within a few hours he had passed away, in the fullness of years and plenitude of powers, without pain or sadness of farewell, leaving behind him a host of pupils who will ever remember him with deep affection and gratitude.

Nihil tetigit quod non ornavit; fama semper vivat!

WILLIAM A. BONE.

SIR WILLIAM SMITH, C.B.

THE death of Sir William Smith, the well-known naval constructor, took place at Craiglands, Herne Bay, on Sept. 16. Though he was not fortunate enough to fill the office of Director of Naval Construction, there have been few in the Admiralty service with a higher reputation, and as Superintendent of Construction Accounts and Contract Work during the period 1902-12, he held a position second only to that of the directorship itself.

Born at Portsmouth on April 4, 1850, William Edward Smith began work in the rope-house at Portsmouth at the early age of eleven, but at fifteen became a shipwright apprentice, and four years later, as the result of a severe competitive examination, gained a scholarship at the Royal School of Naval Architecture and Marine Engineering at South Kensington. Passing out in 1873 as an assistant constructor, he was employed on the designs of the old ironclads *Northampton*, *Colossus*, and *Inflexible*, and later on succeeded Sir William White as instructor in naval architecture at Greenwich. Returning to the Admiralty, in 1887 he was appointed Inspector of Contract Work and later on was concerned with the designs of many of the ships built under the Naval Defence Act of 1889.

During his forty years' active career Smith served under Sir Nathaniel Barnaby, Sir William White, and Sir Philip Watts, and it was under the latter that he held the important post of Superintendent of Contract Work. From this appointment he

Supplement to NATURE

No. 3179 OCTOBER 4, 1930

Reviews.

Contributions to the History of British Surgery.

Plarr's Lives of the Fellows of the Royal College of Surgeons of England. (Thelwall Thomas Memorial.) Revised by Sir D'Arcy Power, with the assistance of W. G. Spencer and Prof. G. E. Gask. Vol. 1. Pp. xxvi + 752. Vol. 2. Pp. 596. (Bristol: John Wright and Sons, Ltd.; London: Simpkin Marshall, Ltd., 1930.) Cloth, 42*s*. net; half bound, 57*s*. 6*d*. net.

THE published registers of a college are not usually books of wide interest, but the two volumes of "Plarr's Lives of the Fellows of the Royal College of Surgeons of England" which have just been issued, edited by Sir D'Arcy Power, are very much more than a biographical register, for they provide a history of English surgery during the last hundred years. The Royal College of Surgeons in London was founded in 1800 to take the place of the Corporation of Surgeons, which had separated in 1745 from the joint Company of Barber Surgeons but came to an end through the negligence of its court after a life of about half a century. The College was thus the direct legal successor of the various guilds and companies into which the surgeons of London had successively grouped themselves since the middle of the fourteenth century. In this capacity the College continued to perform the important office of examining and licensing would-be practitioners of the "art and science of surgery", granting to the successful candidates its diploma of membership.

From its very foundation, however, the College was also entrusted with the care of the great collections John Hunter had gathered together to illustrate life in all its branches, which had been purchased for the nation in 1799, six years after Hunter's death. Much money was expended both by the Government and the College on the satisfactory establishment of the museum in Lincoln's Inn Fields at the beginning of the century; but it was not until 1830 that the catalogues began to be published, chiefly through the labours of Richard Owen, who had been appointed an assistant in the museum in 1826. In 1828 the first librarian, Robert Willis, was appointed; and in the early 'thirties the College was rebuilt, practically in its present form.

The College was thus firmly establishing its important position in the medical education of Great Britain, organising and making efficient its museum and its library, and in 1843 this good work was completed when a supplemental charter was obtained incorporating the College as the Royal College of Surgeons of England and instituting the order of fellows. The first fellows were to be elected by the Council from among the members—not less than 250 or more than 300 were to be elected within three months, and further fellows were to be added at discretion in the first year; after that, election to the fellowship was to be decided by a special examination supplemental to the examination for the diploma of membership. This very important development was chiefly due to Brodie; and, as is stated in the account of him in the collection under review, the institution of the fellowship has been largely instrumental in raising the College to be "the exemplar of surgical education to the whole kingdom".

It is, then, with the first 300 fellows elected in 1843 and with all their followers in the fellowship, whose life and work are already ended, that these volumes are concerned. As a preface to the actual lives, the text of the 1843 charter and the list of the first 300 fellows are printed in full at the beginning of the first volume. A perusal of this list will provide the reader with a clearer historical terminus than the mere date '1843' can convey. The great surgeons who had been Hunter's pupils and successors will not be found among the fellows—their labours were already finished when this new

order was established. Brodie is the senior vice-president in the first list of fellows, and other outstanding names are: William Lawrence, Benjamin Travers, J. H. Green, Liston, Ranald Martin, Syme, Cæsar Hawkins, Le Gros Clark, and James Paget; and of the second group of fellows, elected under the terms of the charter in 1844, George Murray Humphry, founder of the Cambridge school of medicine, is the last on the list.

The lives of these men and of their successors at the head of the profession form the body of the work. Each life is headed by a tabulated list of academic and civic (or military) degrees and honours, with the dates of their attainment. The lives follow, on the whole, the admirable models of the "Dictionary of National Biography", though they are not so severely utilitarian—anecdote and reminiscence are freely, but judiciously, drawn upon to make a portrait vivid; for, as the preface states, a considerable number of the fellows have been known to the editors either as their teachers, their contemporaries, or their pupils. Under the more important names, while a sketch has been given of the subject's whole career and general interests, chief attention has rightly been paid to his professional work, and this study is made more valuable by the select but exact bibliography appended to each life. Full references and acknowledgment are also given, in most cases, of the sources from which the material of the lives has been drawn. As an example, the most important article—Lister—which runs to nearly a dozen pages, gives a sufficient outline of his life and includes an essay, woven round his research and teaching, on "Antisepsis ensuring Aseptic Surgery"; and finally the reader is referred to the "Collected Papers", and to a number of biographies and general articles. But while there are many lives of detailed interest, there are many also which come to little more than a list of appointments gathered into a few lines. It is at first sight a little disappointing that more information should not have been forthcoming about many of these lesser figures. Possibly the publication of these volumes in their present form will elicit additional information from sources which have not been tapped.

The labour of collecting the material for these lives was undertaken by the late librarian of the College, whose name appears in the title, and to him is largely due the credit for such completeness as has been obtained, particularly in the accounts of the lesser men. The editors have prefixed a memoir of him to the collection. Victor Plarr in early life had been a member of the Rhymers' Club, that brilliant but tragic group of poets in the 'nineties, and some of his verses may still be met with in the anthologies of to-day. But for more than thirty years he was librarian of the College and did much useful work, including the completion of the catalogue of the library, which had been started by his predecessor. The volumes now issued will form a lasting memorial to his labours; but the editorship of Sir D'Arcy Power ensures that the student of medical history will find here not merely a collection of lives but also a series of valuable contributions to the history of British surgery.

The period covered begins before the introduction of anæsthetics and passes right through the conflict of opinion over Lister's teaching of antisepsis—here may be found lives both of his opponents and of his supporters and successors, down to the most recent times. The student can find, under the appropriate names, the history of ovariotomy and of the introduction of abdominal surgery, and the rise of scientific ophthalmology and other specialisms. Here also are many names important in the history of the Indian Medical Service. The rise of the modern science of public health is recounted in the lives of Sir John Simon and his fellow-workers. The excellent account of Sir Victor Horsley provides a detailed and worthy summary of his varied and important researches. These are but a few examples, and beside the pioneers and heroes of surgery itself, the amateur of medical history will find much to note in the varied pursuits to which many of these fellows turned aside and in which also they gained success. Many of the leading figures in the development of natural science in the last century are here—Richard Owen, Gideon Mantell the geologist, Bennett, one of the early investigators of Australian zoology, Busk the palæontologist. There are heroic missionaries, and even one bishop. Literature has had her worthy followers in this section of the medical world, and, as might be expected among surgeons, there are several artists of merit, of whom Seymour Haden may be mentioned. He is so deservedly well known as an etcher that his important career as a surgeon, here outlined, may be easily forgotten.

All who care for the history of science must be grateful to Plarr and to Sir D'Arcy Power and his fellow-revisers for their labours, which have so well supplied a long-felt need; and to complete the usefulness of "Plarr's Lives" the editors promise "a supplement every ten years". W. R. L.

Colloid Miscellany.

(1) *Kapillarchemie: eine Darstellung der Chemie der Kolloide und verwandter Gebiete.* Von Prof. Dr. Herbert Freundlich. Band 1. Vierte unter Mitwirkung von J. Bikerman umgearbeitete Auflage. Pp. viii + 566. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1930.) 39 gold marks.

(2) *Die Globuline.* Von Dr. Mona Spiegel-Adolf. (*Handbuch der Kolloidwissenschaft in Einzeldarstellungen,* herausgegeben von Prof. Dr. Wolfgang Ostwald, Band 4.) Pp. xv + 452. (Dresden und Leipzig: Theodor Steinkopff, 1930.) 33 gold marks.

(3) *Traité de biocolloïdologie.* Par W. Kopaczewski. Tome 1: *Pratique des colloïdes.* Deuxième édition entièrement remaniée et mise à jour. Fascicule 2: *Mesure des concentrations moléculaires et ioniques.* Pp. 165-361 + vi. (Paris: Gauthier-Villars et Cie, 1930.) 40 francs.

(4) *Colloid Symposium Annual (formerly Colloid Symposium Monograph): Papers presented at the Seventh Symposium on Colloid Chemistry, Johns Hopkins University, June 1929.* Edited by Prof. Harry Boyer Weiser. Pp. viii + 300. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 22s. 6d. net.

(5) *The Chemistry of the Colloidal State: a Textbook for an Introductory Course.* By Prof. John C. Ware. Pp. xiv + 313. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 18s. 6d. net.

(1) IN the welter of books on colloid chemistry, Freundlich still stands like a great rock in a weary land. The new edition indicates that his great achievement is not to remain as a venerated antiquity; indeed, the growth of the subject is so rapid that the work is now to appear in two volumes, each as large as the original edition of 1909. The classical treatment of surface action originally adopted was so soundly conceived that little alteration in the general scheme has been found necessary to accommodate the additional matter now available. Hence this first volume includes the actual "Kapillarchemie", together with consideration of the kinetics of formation of new phases and the Brownian movement—the detailed treatment of sols and gels being reserved for the second volume. The increase in size is not due to the process of accervation so common in text-books, or to any sensational new developments, so much as to an increase in the intensity of our knowledge of domains hitherto incompletely explored. The author has not hesitated to prune in order to make room for recent work, which is nevertheless frequently introduced in an unobtrusive manner.

Among the new matter in this edition, an extended discussion of the relations between chemical composition and surface tension has been rendered necessary by the recent work on parachors. Adsorption is another branch of the subject which has been brought up-to-date, and in view of the tendency to deal experimentally to such a large extent with charcoals and silica gel as adsorbents for gases and vapours, a short section on the action of metals in this direction is to be welcomed. The portion of the work dealing with electrical phenomena at surfaces has also been extended, and throughout one finds that careful modification of statement in the light of experience which has characterised the earlier editions. It would indeed be difficult to find any important piece of work within the scope of the subject and capable of summarised treatment at the present time which has not been adequately dealt with.

(2) The increase in intensity of colloidal research during the last twenty-five years is indicated also by the important monograph of Dr. Spiegel-Adolf on the globulins. These proteins, even apart from their intrinsic interest, will always have a special appeal to English physiologists on account of the fundamental investigation of them by Sir William Hardy and the subsequent work of other English biochemists. The globulins have not hitherto received in the literature of the proteins the attention which their importance warrants, and it is very convenient to have in one volume such a masterly account of their behaviour. Hitherto such information has remained scattered through the numerous journals in which it was originally published, and, indeed, some of the matter here included has not been published before.

Although the greater part of the work is naturally devoted to the physical chemistry and colloid chemistry of the globulins and their reactions with acids, bases, and salts, there is an interesting section on their importance in biology and medicine which should appeal to the serious student of human physiology and pathology. In completeness and clarity this monograph leaves nothing to be desired.

(3) This second portion of the first volume of Prof. Kopaczewski's treatise represents a distinct advance in French scientific text-books, which hitherto have too often been written with an airy detachment from work carried out in other countries. The references to literature are reasonably numerous and

have not been dictated by geographical considerations. One would expect, however, in a work of this kind some mention in the chapter on osmometry of the determinations of the molecular weight of hæmoglobin by G. S. Adair, as direct measurements of osmotic pressure of biological substances have so seldom been made. The other chapters deal with cryoscopy, conductivity measurements, and the determination of *p*H. The usual methods are described, illustrated with diagrams which are mostly clear enough and large enough to be intelligible, and the tables of results of the most varied nature make interesting reading even for those who will never carry out the determinations themselves.

The main purpose of the whole work is seldom lost sight of, and special apparatus for biological use is a feature of the author's material; and while those engaged in practical work in this sphere may prefer to use more detailed works on the various subjects, this volume will appeal to those whose needs are somewhat broader.

(4) The unsuitability of the use of the term 'monograph' for a work containing twenty-three papers by as many different authors has been recognised by the substitution of the word 'annual' in this seventh year of issue: no doubt in time 'symposium' will give place to some term more descriptive of the occasions when these papers are presented. In general quality the contributions are well up to the standard which readers have come to expect from this publication, and in variety of subject ensure an appeal to a wide circle. It is almost invidious to select separate papers for comment, but the two papers on adsorption and crystal growth carry an interesting subject a stage further in definiteness and are distantly related to the one on the taking up of dyestuffs by hydrous oxides. Again, the articles on clays and the nature of flow have a marked practical bearing; the perennial fascination of gels is indicated by three papers on different aspects of their behaviour, and adsorption and the measurement of the surface area of adsorbents also claim attention. Biological problems are represented by three papers, including one on the projected methods of analysis of bacteria in quantity.

One has the feeling, however, that both the meetings and the report of them in this volume would be improved by the selection of a few dominant issues, to be treated with less detail of experimental work than is here included. Discussions on the papers are not included in the book, and there seems no direct way in which criticism of the papers could be brought forward by anyone not at the meeting. There is no doubt, however, that this annual meeting of American colloid chemists performs a useful function, and many will wish that a similar event might be organised in Great Britain.

(5) Dr. Ware states in his preface that "the purpose of this text is to present the fundamentals of colloid chemistry as they are disclosed by an analysis of the material available at this time and not in accordance with the facts of twenty years ago", as he alleges that in the elementary books on the subject both material and method of presentation are very largely obsolete. One therefore hoped to find in this volume a lucid and up-to-date account of a growing science; unfortunately, it is so marred by inaccuracies in detail that it would be inadvisable to place it in the hands of any but a very intelligent student. On the very first page the criterion of size of particles is stated to be insufficient as a definition of the colloidal state, but no clear definition is given, and the next forty pages are devoted to a description of some of the methods used to determine particle size. This discussion, and indeed the whole of the first half of the book, must leave the student wondering when the materials which have these queer properties are going to appear, for he has to wait until p. 170 before he is allowed to know how the simplest colloidal solution is made. His difficulties will be further increased if "any source of light falls at any angle on any particle" (p. 87), or if he uses a large block of uranium glass with the cardioid condenser (p. 11). The author is particularly pleased with a photograph of the Brownian movement showing a series of wavy lines as indicating the 'vibratory' movement of the particles, and gives the usual diagram of erratic lines with apologies; he does not seem to realise that the photograph was obviously taken with a moving sol or a moving plate (p. 110). On p. 224 the reader is told that particles in emulsions do not carry an electric charge; while on p. 250 the swelling of rubber in benzene is quoted as curious behaviour on the part of a *lyophobic* colloid.

These examples of ill-digested statement are casually selected—there are many more; and while the reviewer is not in agreement with the order of presentation, there is little object in discussing that while the facts presented are so inaccurate. The author suggests that to begin with Graham's experiment on dialysis produces "a combination of entertainment and confusion"; it would be difficult to find a more suitable expression for the results of his own work. P. C. L. THORNE.

Wave Mechanics.

(1) *An Introduction to the Study of Wave Mechanics.* By Prof. Louis de Broglie. Translated from the French by Dr. H. T. Flint. Pp. vi+249. (London: Methuen and Co., Ltd., 1930.) 12*s.* 6*d.* net.

(2) *Wave-Mechanics.* By Prof. Arnold Sommerfeld. Translated from the German edition by Dr. Henry L. Brose. (Supplementary volume to " Atomic Structure and Spectral Lines ".) Pp. xii + 304. (London: Methuen and Co., Ltd., 1930.) 21*s.* net.

HERE we have two books on wave mechanics dealing with the most recent advances in theoretical physics, written by two distinguished authors, each prominent in his own country in the ranks of constructive thinkers. It is of great interest to compare the imaginative work of Louis de Broglie with the more critical and exhaustive treatment of Arnold Sommerfeld.

To de Broglie (1924) we owe the almost bizarre conception which led later to the more complete formulation of wave mechanics by Schrödinger. Every particle possesses some of the attributes of a wave. A particle in motion must be associated with a certain periodicity and with a wave-length, the latter calculated very simply by dividing Planck's constant by the momentum of the particle. This relation is in some measure imposed by the fundamental principles of relativity. A ray of light possesses corpuscular properties, but the light corpuscle is guided by a wave. Such was the paradoxical view which suggested itself to the French physicist. At first it seemed to many only a fanciful and unpractical vision, but the young man's vision led to unforeseen experimental and theoretical developments. Several experimenters brought forward evidence, somewhat vague at first but later clear and definite, to show that moving electrons do behave as though they were controlled by waves when they encounter reflecting surfaces or thin films of matter. Even this experimental evidence would probably not have attracted so much attention, had not the theory of wave mechanics been developed in Schrödinger's papers of 1926 and 1927.

The new method is based on the century-old work of Sir William Hamilton, of Dublin, on the relation between optical and dynamical principles. The principle of Fermat in optics makes the time a minimum for the path which is actually taken by a ray of light travelling from one point to another. This is analogous to the principle of least action, which asserts that a certain integral representing the action has a stationary value for the actual trajectory of a particle. Classical dynamics presents a close analogy to geometrical optics; quantum mechanics presents a close analogy to physical optics. Instead of Fermat's principle we must now employ the principle of Huygens, according to which any point which is reached by a wave becomes the origin of a secondary wavelet which spreads outwards with the same velocity as the original wave. This principle may be expressed in a way familiar to mathematicians as a differential equation involving a complex quantity which Schrödinger calls ψ. The fundamental equations of mechanics must be replaced by a wave-equation in configuration space.

It has been said that Englishmen, who incline to concrete ideas, are less readily accessible to progressive abstraction than the older peoples of the Continent. Certainly many of them confess that they favour a 'picturesque' (*anschaulich*) description of physical phenomena whenever that is available. What, then, is the meaning of Schrödinger's field scalar ψ, or what is the interpretation of his waves? At first it seemed as if the experimental physicist were to be made happy with a concrete representation. The simplest idea is that which regards the particle or the electron as constituted by a group of waves; it is a 'wave packet'. " Unfortunately, when we pass to the domain proper of the new theory it appears scarcely possible to support this idea which is so attractive on account of its simplicity. . . . If they were simple wave packets the particles would have no stable existence." On another view, formerly supported by de Broglie, the particle is considered as a singularity in a wave phenomenon, but to this there are serious objections and it is not discussed at length in his present work. Another suggestion was published in his report to the Fifth Solvay Congress and may be called the theory of the pilot wave. The wave is considered as a reality and as occupying a certain region of space, while the particle is regarded as a material point having a definite position in the wave which serves to guide it on its way. This view also meets with serious difficulties and can only be retained by giving it a modified form.

Schrödinger attempted to interpret his field scalar, ψ, by connecting it with the density of electrical charge, and in dealing with the one-electron problem he obtained striking results by making the product of ψ and $\bar{\psi}$, the conjugate complex quantity, proportional to an electric

density. It is, however, difficult to see how this is to be generalised so as to apply to the case of many electrons. Sommerfeld refers to the view that the charge of the electron is continuously distributed in space as a somewhat unattractive hypothesis, and says: "We refuse from the outset to take literally the charge-cloud to which Schrödinger's theory leads. Rather we shall retain the well-founded view that the electron is point-like in form or at any rate is a configuration of sub-atomic dimensions." He concludes that the charge-cloud can have only a statistical meaning. "Giving up the idea of individual orbits we regard the charge-cloud as the sum total of possible paths of the electron and imagine the average time of stay of the electron in each individual position as determined by the charge-density at that point." On this statistical view, first given a logical basis in the papers of Born, the wave becomes no more than a purely symbolic and analytic representation of certain probabilities, and no longer constitutes a physical phenomenon in the old meaning of the term.

There seems to be little doubt now that the statistical interpretation, unwelcome though it may be, lies closer to the real truth than the earlier suggestion. It has the advantage that it harmonises with the "uncertainty principle" of Heisenberg, for Bohr has shown how the interplay of wave and particle concepts may be closely related to the lack of precision which is inherent in all physical measurements, and how the mathematical formulation is an expression of this unavoidable uncertainty. In conformity with this view, the ψ-function itself is only a mathematical auxiliary quantity, and it is its *Norm* (the German expression for the square of the absolute value), when multiplied by e, that has a real physical meaning, namely, the density of charge. In the same way, the electromagnetic field intensities, which satisfy the differential equations of Maxwell, may also be regarded as mathematical auxiliary quantities introduced for calculating the actual physical relationships between the energy and the motion.

As Dirac has pointed out, the trend of modern theory makes things less easy for the learner of physics. "The new theories, if one looks apart from their mathematical setting, are built up from physical concepts which cannot be explained in terms of things previously known to the student, which cannot even be explained adequately in words at all"!

All those who attempt to follow with halting steps the strides made by the expounders of the new wave mechanics will welcome these two volumes. The translators and the publishers are to be congratulated on the accomplishment of such imporant work, and many English readers will be grateful to Dr. Brose for providing at the end of Sommerfeld's book a list of German expressions and their English equivalents.

H. S. ALLEN.

Experimental Research on Cancer.

Some Aspects of the Cancer Problem: an Account of Researches into the Nature and Control of Malignant Disease commenced in the University of Liverpool in 1905, and continued by the Liverpool Medical Research Organization (formerly the Liverpool Cancer Committee), together with some of the Scientific Papers that have been published. Edited by Dr. W. Blair Bell. Pp. xiv + 543 + 90 plates. (London: Baillière, Tindall and Cox, 1930.) 63*s*. net.

THE aims and objects of this book are clearly set out on the title-page, and the work of the Liverpool Medical Research Organization is sufficiently well known to medical and pathological readers to need no introduction here. Since practically the whole of the contents have appeared previously in various scientific and medical journals, it will not be necesary to review the work in detail. Speaking generally, it may be said that this large volume is in the nature of an *apologia pro vita sua* on the part of the director and the Organization as a whole, and it concludes with an earnest plea for more financial assistance so that the work may go on.

As is the case when claims are made for therapeutic measures in malignant disease, this Organization has in the past encountered a great deal of criticism and hostility. It is well known by those attending meetings in recent years that the attacks have frequently been made with extreme bitterness, so that to disinterested observers it has appeared that whilst scientific problems have been forgotten, personalities have held the day. It naturally occurs, therefore, to look through the book to see what Prof. Blair Bell has to say to his enemies. The author or editor of a monograph has had a wonderful opportunity of hitting back at his attackers without their being able to reply except by publishing another monograph, but one is struck by the fact that Prof. Blair Bell entirely avoids personalities and does not in the least take advantage of his position as editor of the volume. One must admire the fairness of the editor's mind and

congratulate him on overcoming what must have been a severe temptation. Briefly, the contents of the book are as follows :

First, the introduction leads up to the hypothesis of the Liverpool school that malignant disease is similar to chorion in its power of invading normal tissues. From this the whole thesis is built up, and the editor points out that the adoption of lead as a therapeutic agent was due to the well-known fact that this metal causes abortion, possibly by destroying the chorion epithelium. It follows naturally that there must be a great many pitfalls in so wide a type of argument, and it must be admitted, at least by the reviewer, that the collected papers which appear in the later sections of the book do not altogether allay the various doubts arising in the mind. The first series of papers is concerned with physico-chemical considerations on cell membranes by a group of workers under Prof. Lewis. The majority of these observations are of a negative type; for example, the hydrogen ion concentration of the blood in cancer is shown not to differ from that of ordinary blood.

Then follows a long series of investigations by a group of biochemists on the measurement of the metabolism of isolated tissues, working with the methods of Prof. Otto Warburg. It will be remembered that Prof. Warburg showed the widespread nature of the property of glycolysis—conversion of carbohydrate to lactic acid—in all classes of tissues in the absence of oxygen. Only certain kinds of tissue, however, are able to continue producing lactic acid when they are placed in oxygen. At first the suggestion was made that this property was characteristic of tumour tissue, but recent work has made untenable this view of aerobic glycolysis as a specific defect in tumour tissue. Warburg himself, in a paper translated in the volume under review, recognises this fact. This being so, the somewhat elaborate investigations on the metabolism of chorionic epithelium lose some of their interest. Certainly, the fact that chorion has a positive 'U-value' is no criterion of its supposed malignancy, since it is now generally agreed that there are a number of examples of malignant tissues with negative 'U-value', and that this classification is unsound and must therefore be abandoned.

Metabolic studies designed to show the possible mechanism of the action of lead on tissue glycolysis are also included. The fact is recorded that minute concentrations of lead may actually increase tissue glycolysis. Otherwise there appears to be little difference between the action of lead and any other heavy metal. The poisonous effect of heavy metals on enzyme action is a well-known phenomenon, and we cannot agree with the statement on pp. 69-70 that hitherto the actions of poisons on enzyme action have not been found to follow a unimolecular law. In fact, several frequently quoted examples, such as the experiments of Euler and Svanberg on poisoning of saccharase action by aniline, come to mind.

Certainly, therefore, the metabolic measurements, whilst of some interest considered on their own merits, do little to support the general theme with which the book is concerned, namely, the treatment of cancer with lead preparations. There is no evidence from metabolic measurements that the action of lead is exceptionally valuable in destroying the cancer cell by depriving it of the energy necessary for its growth, under conditions where it does not also damage normal tissues to at least the same extent. In addition, the effect of lead in this respect does not differ from that of other metals (p. 511).

This section is followed by a long series of pharmacological observations on lead, the preparation of suspensions and colloidal solutions of the metal, and some observations on organic lead compounds. The changes in the blood during lead therapy are also described at length, and the latter part of the book is concerned with the treatment of cases. Perhaps the most interesting part of the whole work appears on p. 458, where the editor has set out in tabular form the results of their treatment from November 1920 to November 1928. In all, 566 cases were treated, but of these 360 died before the treatment could be completed and a further 77 after the treatment. Various others died of concurrent infections, and some refused treatment. Of the remainder, it is believed that 2 were completely cured but died of other affections later, whilst in 12 the disease was completely arrested, and in 51 the Organization considered the cure had been complete. This tabulating of the results is undoubtedly the most valuable part of the book, as it will enable future investigators to judge whether the risks, etc., of the treatment are justifiable.

In conclusion, a word of praise must be said concerning the general lay-out of the book. The indexing is very good from the point of view of both reference and subjects ; the amount of work involved in collecting the reprints, etc., must have been very great indeed. As to whether the book will be of permanent value and so justify all this reprinting, time alone will prove. The general impression given by reading the work is that the

investigators have strained every argument to support their theory, with the result that in many instances they would rather appear to beg the question. For example, on p. 511 the author does not appear to be quite clear about the Aschheim and Zondek test for pregnancy. Whilst it is true that the presence of a growth-promoting hormone has been noted in the urine in certain cases of cancer (among many other conditions) by these authors, the same principle is not that upon which the pregnacy test is based. This latter test is dependent upon the demonstration of the presence of a luteinising hormone affecting the ovaries and having no effect on general bodily growth in experimental animals. The use of this, therefore, to assist the argument for an analogy between pregnancy and cancer, loses much of its point.

As no general review of modern cancer research work would be complete without a consideration of the work at Liverpool, this volume, in presenting the view of the Liverpool school up-to-date, is of considerable value.

Mathematical Physics.

(1) *Foundations of Potential Theory.* By Prof. O. D. Kellogg. (Die Grundlehren der mathematischen Wissenschaften in Einzeldarstellungen mit besonderer Berücksichtigung der Anwendungsgebiete, herausgegeben von R. Courant, Band 31.) Pp. ix + 384. (Berlin: Julius Springer, 1929.) 19·60 gold marks.

(2) *The Electromagnetic Field.* By Max Mason and Warren Weaver. Pp. xiii + 390. (Chicago: University of Chicago Press; London: Cambridge University Press, 1929.) 27*s.* net.

THE scope and quality of the two works under review are very different, but they are both concerned with branches of theoretical physics, and attack them rather from the point of view of the pure mathematician. This raises an important question of pedagogy, on which there may be differences of opinion. In introducing the differential calculus, for example, is it best to base it on crude ideas about the tangents of curves, or should we begin with the full machinery of the theory of limits? Most teachers adopt the former course, for the reason that it quickly opens out wide ranges for application, whereas, though the logical introduction may sharpen the student's faculties, he may become so busy suspecting the soundness of all the ordinary mathematical processes that he will never learn why anyone should ever want to differentiate anything.

The same divergence applies with even more force to the subjects of theoretical physics. The theory of attractions was developed to study such things as the figure of the earth and the electrical capacity of condensers, and most students learn it for such purposes. The teacher therefore aims at a rapid introduction, making the results appear reasonable to common sense, and opening the subject up as fast as possible so as to show the applications. If this is to be done, it is not admissible to enter into the noble sport of axiom-chasing, but the consequence is that every teacher will remember some clever student who objects to the looseness of the presentation. The student is really experiencing the inherent difficulties of the subject itself, but in trying to puzzle them out has found the weakness of the argument, and naturally blames that. Such troubles should be removed as soon as they are felt, but this is a different thing from carrying the whole exposition through rigorously from the start: for to do that would be to suggest many other difficulties the student has not yet perceived, which will give him far less trouble later when he is more familiar with the whole subject. The present works will find a most useful place in this way as commentaries to be read by a student who has already gained some knowledge of the subjects but has the tidy mind which cannot for a moment tolerate results, however reasonable, unless he can follow every logical step in their derivation.

(1) Prof. Kellogg has written so admirable a book on gravitational attractions that the above comments are perhaps a little ungracious to him. The excuse for them lies in a certain disparity between the first and the last part of the book. Thus the beginner will find that the first three chapters, and a few other parts of the book, will give him all that he needs for an elementary knowledge of the principles of potential theory. But interspersed with this he will find rigorous proofs of such things as Green's theorem, based on the theory of sets of points and the rest of the apparatus of pure mathematics. Seeing how elaborate the discussion becomes, he will be impressed with the difficulty of the subject, and there is a danger that he will think that this difficulty extends to all the applications. On the other hand, the advanced student, who will be a pure mathematician and not a physicist, will not want to waste his time over the elementary part, but will go right on to the rigorous proofs, integral equations, and existence theorems which constitute the important part of the book.

Among all this excellent matter we may single out as of special interest the historical account in

the last two chapters of the various attacks on the fundamental existence theorem. This is a brilliant piece of work, which describes and criticises the successive attempts to prove the existence of the potential, and their limitations ; it will be of great interest to those who are not specialists in potential theory as well as to the experts.

(2) The book of Messrs. Mason and Weaver does not contain any such advanced mathematical theory, but is a straightforward working out of the ordinary principles of elementary electrical theory with a careful analysis of the postulates involved. It falls into four chapters, each of which enters in detail into the principles concerned and also gives many useful examples. The first two traverse the subject of electrostatics. We may single out one point in the treatment which is superior to that of most text-books, and this is the early introduction of the idea that the potential may have a discontinuity at the surface of a conductor ; much of the confusion of thought about the Volta effect arises from the unwarranted assumption, made in most elementary treatises, that the potential of the conductor is the same as that just outside. The third chapter, on magnetism, is novel in that it takes as starting-point the magnetic interaction of electric currents, instead of beginning with permanent magnets. Consequently the vector potential comes in very early, and its curl, the magnetic induction, becomes more fundamental than the magnetic force. The last chapter discusses the field equations of Maxwell in the same detailed manner.

We may only comment on a rather vehement dislike expressed for the ether, which has an old-fashioned flavour. The ether is now usually only regarded as ' the subject of the verb to undulate ', and should have passed into a state where it is beyond the passions. The work goes perhaps a little too slowly to be used as an introduction to electrical theory, but it may be recommended for students who were not contented by their first reading of the subject, and especially for those who are more interested in logical principles than in the applications.

Small Talk about Linnæus.

Linné und Berlin. Von Felix Bryk. Berliner Festschrift zu Linné's Hundertfünfzigstem Todestage, 1778–1928. Pp. xv + 59. (Neubrandenburg : Gustav Feller, n.d.) n.p.

THIS seems to be a publication intended for the collector rather than for that large circle which is genuinely interested in the scientific work of Linné. The title scarcely indicates either its subject or the variety of curious and entertaining matter which the booklet contains. It expresses indeed little more than the fact that the hundred-and-fiftieth anniversary of Linné's death, in 1928, was celebrated more in Berlin than in any other place, and that an article on Linné's relations with Berlin, which Dr. Bryk of Stockholm wrote for the *Berliner Tageblatt*, but which did not appear, is now first published. The editor, C. L. Hansen, has, however, included the address Linné as artist, delivered on that occasion by Dr. Bryk, as well as a lecture that he gave on Linné from the bibliophil point of view.

The value of the book to the collector does not depend only on the small size of the edition, 67 copies : it will be prized also for its facsimiles of Linné's diploma from the Berlin Academy (signed, be it noted, by two Frenchmen, Maupertuis and Formey), Linné's letter of acknowledgment to Formey, and Linné's original sketch for his arms ; also, possibly, for the facsimile of part of the proof of the *Berliner Tageblatt* article. None of these has been published previously. Other facsimiles comprise the notification of Linné's death and numerous rough drawings by Linné himself, among which the most notable is the diagram of an egg in section, intended for his arms but objected to by the herald, Tilas, who eventually admitted the egg under protest but not without the decent covering of its shell.

Linné's relations with Berlin may be summarised in the facts that Celsius, then in Berlin, got a review (written by Linné) of the " Lapland Journey " translated into Latin and published at Nuremberg ; that Gronovius brought him to the notice of the Berlin Academy, with results already mentioned ; and that Gleditsch confirmed Linné's views on the sexuality of plants by a notable experiment. The female palm which Gleditsch fertilised is still growing at Dahlem.

Linné's artistic sense appears not so much in the rough sketches with which he explained his meaning, as in some small head- and tail-pieces, in his care for typographic style, in his accurate appreciation of colour, and above all in his continual praise of the beauty found in Nature. He constantly urged the employment of competent scientific draughtsmen, and Archbishop Benzelius is responsible for the assertion that the Archiater knew more about painting than anyone else in Uppsala.

Linné appears as bibliophil in his formation of a private library and in the bibliographic references

contained in his "Systema Naturæ". The interest of bibliophils in Linné is due partly to the enormous literature concerning him and his work, partly to the difficulty of deciding whether certain theses were due to his pen or to that of their nominal authors, partly to the minor variations in title-pages and the like so dear to the collector, and partly to the excessive rarity of some publications. The rarest must surely be the panegyric of which my Lord Baltimore in 1780 printed only two copies. That eccentric travelled through Sweden in a carriage so large that bridges had to be widened for him to pass with his retinue, including two cooks, eight mistresses, but only one physician. His reason for perpetually travelling was that he did not wish to know where he would be buried. Let this digression serve as a sample of the entertainment to be found in Dr. Bryk's enthusiastic pages.

The booklet is well produced and is provided with three indexes: to personal names, to literature quoted, and to place-names. The only serious omission is that of a date of publication on the title-page. F. A. B.

Design and Operation of Chemical Plant.

(1) *Filtration and Filters: an Outline of the Art.* By J. A. Pickard. With a Section on the Mathematical Aspects of Filtration, by A. J. V. Underwood. Pp. 488. (London: Ernest Benn, Ltd., 1929.) 45*s*. net.

(2) *Sulphuric Acid and its Manufacture.* By Dr. H. A. Auden. Pp. viii + 231. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1930.) 16*s*. net.

(3) *A Handbook for Cane-Sugar Manufacturers and their Chemists.* By the late Dr. Guilford L. Spencer. Seventh edition, revised, re-written, and enlarged by George P. Meade. Pp. xix + 560. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1929.) 30*s*. net.

(4) *The Chemistry of Leather Manufacture.* By Dr. John Arthur Wilson. (American Chemical Society Monograph Series, No. 12.) Second edition. Vol. 2. Pp. 497-1181. (New York: The Chemical Catalog Co., Inc., 1929.) 10 dollars.

A GREAT deal of scattered information is available relating to the design and operation of chemical plant. Some of it is contained in technical pamphlets, many of them excellent, which are issued from time to time by the actual plant manufacturers; some of it appears in the form of articles in technical journals; much of it is hidden away in the plant records of the chemical manufacturer. This scattered information may usefully be collected and summarised from the point of view either of plant design or of plant operation.

Of the books under review, the first is of use to the student of plant design; the others deal more particularly with operating conditions.

(1) Mr. Pickard's volume is primarily a useful collection of some four hundred illustrations with appropriate descriptive matter, showing the types of filtering apparatus and plant that are available for dealing with the different kinds of filtering problem. The treatment adopted in the book is almost entirely descriptive; little is said about the quantitative aspect of filtration. The arrangement of the book is somewhat uneven; considerable space is given to gravity oil separators, whereas such a useful appliance as the electrostatic precipitator is barely mentioned. Nothing is said about the effect of precipitating conditions upon the filtering characteristics of the precipitate. The book contains a valuable chapter by Dr. Underwood upon the mathematical theory of filtration.

(2) Dr. Auden's work is essentially a comprehensive notebook on the subject of sulphuric acid manufacture. It is addressed primarily to the student of applied chemistry. In his treatment of the subject, the author does not seek to obtrude his viewpoint to any great extent on the reader. He is satisfied to correlate and submit the opinions and conclusions of other workers in the field, drawn from the vast amount of published data available. In giving copious references to original articles, he provides the reader with a suitable jumping-off ground for a more extended study of the subject.

Chap. xii., on the theory of the chamber process, might well be cast somewhat earlier in the book—say, in place of Chap. ii., which treats of the handling and transport of acid. In many places there is a scarcity of diagrams; in others, too little descriptive matter accompanies the diagrams submitted. These points are small, but, as the work is intended primarily for students of industrial chemistry, the first suggestion would seem an obvious advantage, while the second would prove a decided help to those whose experience of plant has yet to be obtained.

It is remarkable how much information the author has succeeded in compressing into the relatively small space of sixteen chapters and two

hundred and twenty-one pages. That he has carried out a very creditable piece of work there can be no doubt. We have no hesitation in recommending this book to all those interested in the technical development of the sulphuric acid industry.

(3) A new edition of Spencer's well-known handbook on the cane sugar industry has been issued. Five new chapters are included, dealing, respectively, with the economic phases of the sugar industry, the keeping and refining qualities of raw sugars, hydrogen ion control, colour determination in the sugar industry, and fermentation. The book is a model of what a handbook to a large industry should be. The author describes clearly and completely the kind of plant that is used at each stage of the process, and discusses fully the design and operation of each plant, both from the chemical and the chemical engineering points of view. The book might equally well form a basis for a detailed chemical engineering study of the design and lay-out of a cane sugar factory.

(4) Vol. 2 of Dr. Wilson's important treatise on leather manufacture deals from the physical chemical point of view with the practice and theory of both vegetable tanning and chrome tanning, as well as of numerous other special tanning methods. The underlying principles of the various processes to which the leather is afterwards submitted are described very clearly and in great detail. Finally, the chemical and physical properties of the finished leather are considered both from the theoretical and practical aspects.

The leather industry, although one of the oldest industries in the world, is actively developing in numerous directions, thanks to the application of physical chemistry to the investigation of its problems and processes, and this book is a first-rate account at first hand of the newest developments in leather chemistry, written by one of the leading and most active workers in this field. It is a fascinating book, not only for the leather manufacturer, but also for the physical chemist and the chemical engineer.

Dinosaurs in East Africa.

The Dinosaur in East Africa: an Account of the Giant Reptile Beds of Tendaguru, Tanganyika Territory. By Dr. John Parkinson. Pp. 192 + 12 plates. (London: H. F. and G. Witherby, 1930.) 12*s.* 6*d.* net.

IN 1907 the late Prof. E. Fraas, of Stuttgart, discovered at Tendaguru in Tanganyika Territory (then German East Africa) an extensive deposit of bones of gigantic Dinosaurs comparable with the bone-beds in which startling discoveries had already been made in Wyoming, U.S.A. From 1909 until the end of 1912, Dr. W. Janensch and Dr. E. Hennig explored this deposit with remarkable success, and made a great collection of the Dinosaurian remains which are now in the Museum für Naturkunde in Berlin. They also studied the geology of the country, and published a valuable report on the subject, showing that the African and North American formations were of about the same age and had accumulated under similar conditions. Dr. Janensch is also still publishing a series of important monographs on the skeletons as they are prepared. After the war the British Museum undertook to continue the exploration, and among those who were engaged both to collect specimens and to re-examine the geological structure of the district was Dr. John Parkinson, who had already had much experience of field-work in Africa. Dr. Parkinson not only collected materials for a scientific report, but has also prepared a popular general account of his expedition in an attractive little book which is now before us.

Dr. Parkinson deals with a technical subject in a non-technical and entertaining manner, and enlivens each chapter with apt quotations ranging from Shakespeare and Dickens to H. G. Wells. As he proceeds from one aspect of the investigation to another, he imparts to the reader some of the enthusiasm of the discoverer. In less than two hundred pages he succeeds in giving a good idea of the problems which arise for solution.

The main bone-beds of Tendaguru extend over an area about 3½ miles from north to south and 1½ miles from east to west. There are also outlying deposits of similar bones in the surrounding region, all dating back at least to the beginning of the Cretaceous period, some perhaps a little older. The skeletons must have been washed together by river-floods in an estuary or lagoon, which was invaded at intervals by the sea; for there are layers of sand and clay full of marine shells intercalated at intervals in the river sands and clays.

The Tendaguru Dinosaurs themselves are much the same as the Dinosaurs which have been found in the corresponding rocks in North America and elsewhere. One of them, *Gigantosaurus* or *Brachiosaurus*, is interesting as being at least as large as the largest hitherto found in North America, probably well over 100 feet long. They formed the same kind of community, with strange lack of brain-power, yet dominating the world of life.

Dr. Parkinson refers to this strange dominance, and devotes one chapter to the mode of life of the Dinosaurs, and some possible reasons for the extinction of these and all the other giant reptiles at the end of the Cretaceous period when small mammals appeared ready to take their place. He particularly refers to the effect of parasites on the existing mammals of Africa, and suggests that the known change in the flora at the end of Cretaceous times may have led to an increase in certain injurious insects. The mystery still remains, however, for the sea-reptiles disappeared as suddenly as the land-reptiles, and the pterodactyls gave place to birds.

Dr. Parkinson, in discussing the Dinosaurs, brings together much curious information which, though familiar to palæontologists, will be new to most readers; and he concludes with a bibliography which will be useful to those who wish to pursue the subject in detail. We would only add that he might well have included a reference to the late Dr. W. D. Matthew's excellent Handbook of Dinosaurs, published by the American Museum of Natural History, New York. A. S. W.

Orchids.

(1) *Orchids for the Outdoor Garden: a Descriptive List of the World's Orchids that may be grown Outdoors in the British Isles; for the Use of Amateur Gardeners.* By A. W. Darnell. Pp. xx + 467 + 22 plates. (Ashford, Kent: L. Reeve and Co., Ltd., 1930.) 42*s*. net.

(2) *Our Wild Orchids: Trails and Portraits.* By Frank Morris and Edward A. Eames. Pp. xxxi + 464 (130 plates). (New York and London: Charles Scribner's Sons, 1929.) 30*s*.

(1) THE cultivation of orchids out-of-doors has never been developed to the same extent as that of their hothouse allies, but with the increasing popularity of rock-gardening a greater interest is being taken in those species of orchids, mostly terrestrial, which can be grown in the open in Great Britain. So far only a few of the more striking European species such as *Orchis purpurea*, *O. militaris*, *Himantoglossum hircinum*, and various American species of *Cypripedium* have been cultivated at all frequently.

There are, however, many species which, judging from their native habitats, should be hardy in the British Isles and would well repay the trouble of growing them. Mr. Darnell, in the work here noticed, describes all the species which in his opinion fall into the above category. Generic descriptions are also given, while notes on distribution, habitat, time of flowering, and suggested cultural methods are added. A glossary of scientific terms and a short introductory chapter on methods of propagation and importation are also provided. Some of the more interesting species are figured.

In consequence of the wide scope of the work the number of species included is about one thousand, and it will be several years before even a tithe of them can be brought into cultivation. The book, however, should be a useful guide for anyone visiting any part of the world as to which orchids are worth collecting. Unfortunately there are few people who would be able to name the species collected in many countries even with the aid of Mr. Darnell's book. Anyone who has studied, for example, the genus *Habenaria*, of which there are 94 species included in the book, knows how difficult the species are to name even in a large and relatively complete herbarium. For many years it will be necessary to submit specimens of this and other genera mentioned to expert orchidologists in order to be sure of their identity.

Nevertheless, Mr. Darnell's book demonstrates in a convincing manner what a wealth of orchids there is available for growth out-of-doors in Great Britain, and should encourage those interested in gardening to endeavour to introduce as many as possible of such species. When growing, these may be studied more thoroughly by taxonomists than is possible from herbarium specimens alone. Our greater knowledge of the hothouse species can be attributed directly to such study in the living condition.

(2) The fascination which orchids have for the amateur in almost every country is no doubt bound up with the remarkable form and intricate structure of their flowers. For the same reason pictures of orchids are usually relatively more valuable than those of other plants since orchids are more difficult to describe adequately in words. Consequently by obtaining photographs of all the species of orchids growing in eastern North America, the authors of the present volume are rendering a considerable service to science.

However, the photographs, which might with advantage have been taken on an even larger scale, are only a portion of the book. Each species is described shortly and its popular names are given, while detailed notes on habitat, distribution, and flowering period are provided. The bulk of the book is taken up by accounts of the authors' searches for the various species, their adventures

on the way, and their final successes, often accompanied by charming pen-pictures of the areas visited and of the orchids themselves. The photographs, several of which are coloured, are all taken in the field, and therefore show effectively the natural habitat of each species. Keys to the genera and species are supplied at the end, together with a glossary of scientific terms used. The features mentioned above, together with the excellent format, render the book a useful and attractive addition to any botanical library. V. S. S.

Classification of Ore Deposits.

Ore Deposits of Magmatic Origin: their Genesis and Natural Classification. By Prof. Dr. Paul Niggli. Translated from the original German edition by Dr. H. C. Boydell. Revised and supplemented throughout by Dr. Niggli and Dr. R. L. Parker. Pp. xi + 93. (London: Thomas Murby and Co.; New York: D. Van Nostrand Co., 1929.) 9*s*. 6*d*. net.

PROF. NIGGLI has followed his important monograph of 1920 on the function of the volatile constituents in petrology by an interesting essay on their importance in the classification of ore deposits. He adopts the view that an ore is a rock and should be studied as such, and that "ore deposition is a part problem of magmatic differentiation in its widest sense". He regards as magmatic all products that arise originally from the interior of the earth, and holds that "magmatic processes are to no small extent involved in the formation" of even such materials as glass sands and those used for cement and pottery. He divides magmatic products into three kinds: the orthomagmatic, or directly igneous, to which some authorities limit the term; the pegmatitic-pneumatolytic; and the hydrothermal. He remarks that the meaning of the term pneumatolytic has been altered, since it was proposed by Bunsen for volcanic exhalations; but as the essential agent, according to Bunsen's conception, is superheated steam, the modern development seems justifiable. The author's introduction of the term orthomagmatic is useful, as its adoption would avoid the ambiguity as to the implication of the term magmatic.

The author is a master of the principles of physical chemistry, and his treatment of ore formation is throughout clear, though technical, and suggestive. He introduces many new terms, such as 'exogeospheric' for the processes of the atmosphere and lithosphere, and 'endogeospheric' for those of the interior, and 'telemagmatic' for operations that take place remote from the site of the magma.

The author lays stress on the threefold division of ores, based on depth and nature of formation, on geological age, and on geographical distribution. He applies to ores his well-known views on petrographic provinces, and adopts Pacific and Mediterranean groups of ores. That those terms are not used in a strictly geographical sense is shown by the remark that there are many Pacific provinces. His classification develops the well-established gradual passage from the deep-seated orthomagmatic to the superficial or hydrothermal ore deposits. He differs from many economic geologists in his conclusion that "complete sequences of ore deposits are connected with folding movements". He explains the poverty of the Alps in ore deposits as due to the movements which made the mountains having been promptly followed by the sinking of the area as a geosynclinal. There is much to be said for the alternative view that the ascent of the hydrothermal solutions takes place mainly along deep-seated normal faults in regions of tension.

The book refers briefly to a large number of ore deposits and there are naturally a few slips, such as the pre-Cambrian age of those of Mount Lyell, and reference to the titaniferous iron ore of Taberg in Sweden as an example of an orthomagmatic ore of great economic importance.

The careful translation by Dr. H. C. Boydell has been revised and supplemented by Prof. Niggli and Dr. Parker.

Peruvian Antiquities.

Dress and Ornaments in Ancient Peru: Archæological and Historical Studies. By Gösta Montell. Pp. viii + 262 + 3 plates. (Göteborg: Elanders Boktryckeri A.-B.; London: Oxford University Press, 1929.) 15*s*. net.

IT is characteristic of the cosmopolitan learning of our time that this study in Peruvian antiquity should be prepared at Gothenburg, translated into English, and published, with a generous Swedish subsidy, by the Oxford University Press. Besides the splendid ethnographical museum in Gothenburg over which Erland Nordenskiöld presides, more than a score of other museums and galleries have contributed material and illustrations.

For the cultures which preceded the Inca régime, the material is mainly archæological. A sufficient number of actual garments have been preserved by

dry climate, in early graves, to control the interpretation of the vividly pictorial art of the contemporary potters, not only as to the decoration of the clothing, but even as to its shapes and construction. The modelled and painted Chicama pottery is naturally the most eloquent, but the modelled black-ware from the Lambayeque and Trujillo districts contributes much interesting detail. Head-gear, head-ornaments, and hairdressing are, of course, included in the survey; and the difficult question (p. 92) whether tattooing coexisted with face-painting is settled by Dr. Folke Henschen's examination of a piece of mummified skin, which shows dead black "exogenous pigmentation, arisen during life, that is to say, the result of tattooing", though he has not been able to identify the pigment chemically. Its resemblance to coal-dust pigment, in the human lung, supports the obvious guess that soot was used.

For the Inca period, and especially for the culture of the Inca-folk themselves, the evidence is different. The damp climate of the Andes has wrecked most of the original garments, and apparently the pottery does not clearly distinguish between pre-Incan costume and Incan. But the Spanish descriptions, referring, as they do, to the higher ranks of society mainly, and consequently reproducing Inca habits, supply the deficiency of archæological material. Especially valuable, both for garments and for textile processes, are the naïve sketches in Huaman Poma de Ayala's manuscript. Another curious source of evidence is in the myths which describe the divine institution of certain venerable and unalterable costumes; and it is probable that this conservatism, as well as the skilled workmanship noted on p. 195, explains the "surprising consistency in the measurements of Inca shirts found in graves in the highlands, where more clothing was worn and conditions were more favourable for its preservation".

Numerous excellent illustrations and a full bibliography add greatly to the usefulness of this careful and well-written memoir.

Species-Hybrids in Plants.

Artbastarde bei Pflanzen. Von O. Renner. (Handbuch der Vererbungswissenschaft, herausgegeben von E. Baur und M. Hartmann, Lieferung 7, Band 2.) Pp. iv+161. (Berlin: Gebrüder Borntraeger, 1929.) 28 gold marks.

THE eighteenth-century hybridisers—Kölreuter, Knight, Sageret, Gärtner—studied almost exclusively interspecific crosses, although Sageret, like Mendel, gave his attention to pairs of contrasted characters. This method of choosing the most complicated rather then the simplest cases in investigating the laws of heredity continued largely in vogue, with the great exception of Mendel, until near the end of the nineteenth century, and retarded for at least half a century the understanding of these laws. Following the rediscovery of the Mendelian analysis, investigators for many years dealt with variety differences, mainly in domesticated plants and animals. But with elucidation of the Mendelian principles, research on species-hybrids soon began again in such work as that of Baur on *Antirrhinum* and of East on *Nicotiana*. Later genetical work has drifted more and more into the investigation of genera by crossing and cytological study of their species.

This application of the Mendelian weapon to the more complicated problems of specific structure and relationship, in conjunction with chromosome study, together with taxonomic and distributional treatment, is one of the newer and most promising lines of development in genetics. Such studies have already led to important results, and are bringing us to new points of view in phylogeny and evolution.

Prof. Renner has done a valuable service to biology in summarising this recent genetical work on species-hybrids in plants. The first section of his book deals with the F_1 phenotypes, including intermediate hybrids, cases of unlike reciprocal hybrids (especially in *Œnothera*, *Epilobium*, and *Digitalis*), multiformity and vegetative segregation in the first generation. The structure of the pollen, the chromatophores and the chromosomes of such hybrids is discussed, as well as questions of hybrid vigour (heterosis), dwarfing, new formations, and sterility in these forms.

In another section the methods of reproduction and the offspring of species-hybrids are considered at length, including their chromosome behaviour during meiosis. A short chapter is concerned with the cases, mostly quite recent, where a constant hybrid has been produced through a doubling in its chromosomes. Here are cited *Œnothera gigas* and *Primula kewensis*, as well as cases in *Rosa*, *Nicotiana*, *Ægilops-Triticum*, *Raphanus-Brassica*, *Papaver*, *Crepis*, etc.

A final page only is devoted to species-crossing in Nature. This section could have been profitably much extended, but perhaps deserves separate treatment. Following the extensive bibliography there is unfortunately no index.

R. RUGGLES GATES.

Our Bookshelf.

Archæology and Ethnology.

Akan-Ashanti Folk-Tales. Collected and translated by Capt. R. S. Rattray. Pp. xx + 276 + 12 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1930.) 21*s.* net.

WITH this volume of folk-tales, Capt. Rattray completes a series of four works in which the customs, laws, and beliefs of the people of Ashanti have been surveyed. It is by no means the least valuable of the series, for in these stories the mentality of the people is revealed, more artlessly perhaps, but by no means less effectually, than in the analytical studies of the more formal investigations. These *Märchen* have been taken down in the actual words of the narrators just as they were told around the fire at night in the villages. Facing each page of native text on the opposite page is Capt. Rattray's translation, the incidents and persons of the tales being illustrated by drawings by native draughtsmen.

The translation has been made as literal as possible, allowing for the difference of idiom, but without altering the spirit and style of the original. All the tales have members of the animal world for their characters and, as usual, a large proportion are etiological. Although known generically to the native as *Ananse* stories, the spider (*ananse*) is not the hero of each. The stories in which the spider figures are, however, the most spirited and the most humorous. It is interesting to note that this prominence of the spider survives in the *Anancy* of some collections of stories told by American negroes.

Some interesting points relating to the stories are raised by the author in his introduction. He discusses the reason why animals are the actors in these stories, and why a vein of coarseness runs through them which is foreign to the mode of thought and act of the people. In regard to the former, he is of the opinion that it is not due to a confusion of the human and animal world, as has been suggested, but to the fact that it permits of a greater licence than if the names of persons were used; and in regard to the second point, that the fact that the stories are related at night admits of a freedom of action in the representations which sometimes accompany the stories and in the stories themselves which is not allowed by day. Something analogous is to be observed in the apologetic remarks prefacing the stories and in the text signifying that what follows is not to be taken too seriously.

The Archæology of Middlesex and London. By C. E. Vulliamy. (The County Archæologies.) Pp. xx + 308 + 12 plates. (London: Methuen and Co., Ltd., 1930.) 10*s.* 6*d.* net.

THIS volume inaugurates a new series of County Archæologies of which the general editor is Mr. T. D. Kendrick of the British Museum. The need for such a series has doubtless been felt by many students for some time. Although the archæological sections of the Victoria County Histories are still invaluable, it is many years since most of them were written. During the last decade many new facts have accumulated; and fresh interpretation of the facts has profoundly modified many views on the prehistory of Britain.

Mr. C. E. Vulliamy's volume deals with the County of Middlesex and that part of the modern county of London that lies north of the Thames. The area is one which presents special difficulties from both the geological and the archæological points of view—not the least being the fact that a large proportion is under bricks and mortar, and direct evidence is obtainable only at haphazard as excavations for building and other works allow. Hence reconstruction is based to a great extent on museum material—too often, especially when in, or after having passed through, private hands accompanied by inadequate and imperfect data of origin and conditions of discovery. Much of the material also has been dredged from the Thames, and therefore affords little direct evidence bearing on archæological problems. There are also gaps in the time-series in respect of London itself. On this account Mr. Vulliamy sets aside the arguments which have been adduced for a Celtic settlement prior to the Roman, and concludes that is was practically deserted for some time after they left. Mr. Vulliamy makes no attempt to ignore all these difficulties; but this only serves to enhance the value of a book which promises well for the future of the series.

Minoans, Philistines and Greeks, B.C. 1400–900. By A. R. Burn. (The History of Civilization Series.) Pp. xv + 273 + 16 plates. (London: Kegan Paul and Co., Ltd.; New York: Alfred A. Knopf, 1930.) 15*s.* net.

IT is scarcely necessary to stress the difficulties which Mr. Burn has had to overcome in attempting a continuous narrative of events in the eastern Mediterranean between B.C. 1400 and 900, that is, from the supremacy of Minoan Crete to the entry of the Dorians into the Greek world. There is, as he says, "in all human history, no period, no subject either of greater interest or of more profound importance". It would be almost equally true to say there is no period which offers more moot points for diversity of opinion.

Mr. Burn has divided his book into two parts. In the first certain controversial matters are discussed as necessary prolegomena—archæology and the legends, the Homeric question, the language problem, the origin of the Achæans, chronology and the like. For his second part—the narrative—the author claims no originality, and apologises for his temerity in trying to do what is not even attempted in the "Cambridge Ancient History". His fears are unfounded. Not only has he produced an eminently readable and interesting story, but also his wide knowledge of the facts and his critical

ability in handling the evidence enable him to make out a good case for his views on controversial matters. For those who are not specialists in Mediterranean archæology he has produced a narrative which will serve as the necessary framework for the appreciation of opposing arguments on questions in suspense. The free use made of the evidence from legends is eminently skilful and ingenious, in fact, a valuable demonstration of the legitimate employment of this somewhat elusive source.

A Scheme of Babylonian Chronology: from the Flood to the Fall of Nineveh; with Notes thereon, including Notes on Egyptian and Biblical Chronology. By Duncan Macnaughton. Pp. xii + 189. (London: Luzac and Co., 1930.) 7*s.* 6*d.*

An adequate commentary on this book would require a space as great as its text. The author apologises for his temerity in putting forward his theories, and excuses himself on the ground that he has no reputation to lose. He has, in any case, produced a stimulating book in which many of the arguments, astronomical, astrological, and chronological, are suggestive in that they frequently open up a new point of view on a vexed problem. It is interesting to note that he finds, for example, that the flood began on Jan. 6, 3181 B.C. in the Julian Calendar; that Hammurabi's reign falls considerably earlier than is usually held; and that Abraham was born not earlier than 2275 B.C. and not later than 2100, and in any case did not live in the reign of Hammurabi as is generally thought. Another interesting suggestion is that the Hebrew story of the Flood is an independent version, having originated in the Armenian mountains, and thus accounting for the fact that the Babylonian Flood began two days earlier. The fabulous number of years assigned to early dynasties by Berosus is ingeniously interpreted to bring them within a reasonable compass—perhaps the most pregnant suggestion in the whole book.

Astronomy.

The Magic of the Stars. By Maurice Maeterlinck. Translated by Alfred Sutro. Pp. 155. (London: George Allen and Unwin, Ltd., 1930.) 6*s.* net.

A book by a writer with the reputation of M. Maeterlinck must be approached with respect, but to be quite frank we must say that we have left this little volume with our respect greatly diminished. The book is partly an exposition of the latest views of astronomers and physicists on the more general problems of astrophysics, and partly an account of the author's own mystical ideas. Our objections to it are two: namely, that the exposition contains far more inaccurate than accurate statements, and secondly, that the science and mysticism—between which no connexion is shown—are so intermingled that the unenlightened reader cannot tell what is a generally accepted conclusion of science and what a fancy of the author's. It is easy, and generally idle, to quibble at inaccuracies of detail in a book by a non-specialist, and the criticism is particularly futile when the argument of the book requires only the broader aspects of science. We should not raise the matter here if the science in the book were merely the basis on which the mysticism was built, but it is not. It is definitely in the form of an exposition, intended to instruct the ignorant simply for the sake of instruction. When, therefore, we find the author frequently wrong in his statements, and, further, using scientific terms in that indefinite and 'woolly' sense which is fatal to clear thinking, we feel that protest is not only justified but necessary.

Our second objection also must be protected against misunderstanding. We do not object to mysticism, or even to M. Maeterlinck's particular brand of mysticism, although we may not find ourselves able to accept it. What we do dissent from is the random association of ideas arrived at by the scientific method with ideas conceived in some other way. It is profitless and confusing to mix ordinary geological facts and arguments with the notion that the earth is a conscious intelligent being with a purpose in view. When Tyl-tyl says: "There are no dead", we are impressed, but when we read, in an account of the universe of the astronomer, that "there are, strictly speaking, no dead and no cemeteries", we are simply irritated. Books of this kind can have no effect but a harmful one, and we hope that M. Maeterlinck's example will not be followed by other writers with metaphysical doctrines which they wish to impart.

H. D.

Modern Cosmologies: a Historical Sketch of Researches and Theories concerning the Structure of the Universe. By Dr. Hector Macpherson. Pp. vii + 131 + 12 plates. (London: Oxford University Press, 1929.) 7*s.* 6*d.* net.

This little book is a companion volume to the author's 'Modern Astronomy' published a few years ago. It consists of eight lectures delivered under the 'David Elder' foundation in the Royal Technical College, Glasgow, during the winter of 1928–29. The word 'modern' is always somewhat indefinite, and it may perhaps be well to state that, excluding an introduction on Greek ideas and a short initial chapter on the transition from the Ptolemaic to the heliocentric conception, the subject-matter ranges from the work of Herschel to that of the present day. It is treated in the main in a descriptive manner, with numerous quotations and references. There is very little independent criticism, but a conspicuous exception to this statement is found in a discussion of Sir William Herschel's cosmology, in which the author gives reasons for dissenting from the opinion of Struve and Proctor that Herschel abandoned the disc-theory of the sidereal system in his later years.

The book is well constructed and gives an excellent bird's-eye view of our present ideas on the structure of the galaxy, the local star system, and the nebulæ and star clusters. Such a summary is very welcome, but in these days of rapid advance by methods inconceivable to an earlier generation, it is perhaps even more timely that the principles employed by the astronomers of the last century in

dealing with this greatest of astronomical problems should be recalled to our memory for their validity to be re-estimated. The book is excellently illustrated, and the form in which it is reproduced makes it a pleasure to handle.

Tychonis Brahe Dani: Opera Omnia. Edidit I. L. E. Dreyer. Tomus 15. Pp. v + 54. (Hauniæ: Libraria Gyldendaliana, 1929.)

THIS volume completes the sumptuous and scholarly edition of the works of Tycho Brahe which Dreyer began and Ræder has completed. A monument of patriotic piety like this edition may not directly promote astronomical science, but there can be no doubt that it tends to foster an enthusiasm for the science to which Tycho Brahe devoted himself, and neither Dreyer himself nor Denmark as a whole can be charged with failing to take a full share in the progress of astronomy.

The present volume contains two short poems and an index to the whole work. Where portions have been separately indexed, references are given, but the details are not repeated. The original design was to include a bibliography and iconography, but we are told that the omission of these is made good by the copious treatment which Tycho Brahe's works and the literature which has gathered round him have received in Ehrencron-Mueller's Danish Bibliography.

One last word of thanks and congratulation is due to G. A. Hagemann and to the Carlsberg and Rask-Ørsted Institutes, the munificence of which has permitted the works to appear in a form worthy at once of the author and of the loving labour of the editors. J. K. F.

Biology.

Biology for Beginners. By Dr. E. J. Holmyard. (Dent's Modern Science Series.) Pp. vii + 172 + 8 plates. (London and Toronto: J. M. Dent and Sons, Ltd., 1930.) 2*s.*

IN this little book, Dr. Holmyard has organised a very comprehensive course in biology for the pupils in the lower forms of public and other secondary schools. When examining the amount of material which receives consideration, one feels that the author has been a little too ambitious. Although, as he claims from experience, the pupils might grasp all the facts dealt with, one suspects that they might miss the wood for the trees, and it is doubtful whether they would gain a sound knowledge of the general principles of life.

The physiological aspect in biology is probably the most controversial of all. Very judicious handling, therefore, is clearly essential when presenting such a subject to young beginners. By omitting certain facts, that is, by hiding part of the truth, wrong impressions may easily be conceived. The author must plead guilty of this, in some cases. For example, he leaves his readers with the impression that all green plants manufacture starch and that the food of plants is essentially different from the food of animals. In several places, too, terms and conceptions appear which are now out-of-date. The book, unfortunately, contains several points of this nature which, though not exactly errors, might well, with advantage, have been avoided.

Many good illustrations accompany the text, and each chapter is followed by useful questions. The book would probably be more useful to pupils who have already made a still more elementary study of the subject, rather than to actual beginners. It is well written in the author's inimitable style, which makes a free use of humour as a means of maintaining interest.

Further Illustrations of British Plants. By Roger W. Butcher. Drawings by Florence E. Strudwick. Forming with Fitch's Companion Volume to Bentham's Handbook a Collection of Illustrations of most of the Species in the British Flora. Pp. vii + 476. (Ashford, Kent: L. Reeve and Co., Ltd., 1930.) 12*s.* net.

THIS book should prove an invaluable guide to students of the British flora. To trace the identity and relationships of a species is often a difficult problem, and, in such difficult cases, good illustrations are helpful. Illustrations, however, in many so-called handbooks, are often so poor that they are useless to the systematist. The illustrations given in this volume are distinct, and, although in most cases the whole of the plant is portrayed, many of the diagrams are accompanied by enlarged drawings of the more diagnostic features.

The Angiosperms are, of course, very fully represented among the illustrations; but a few Gymnosperms and Pteridophytes are included at the end of the book. Concise descriptions of the habit and habitat of the plant accompany each illustration.

The authors are to be congratulated on their admirable work, chiefly for its clarity and brevity, thus making possible the consideration of a large number of plants in a comparatively small volume. This work, together with Fitch's "Illustrations of the British Flora", will undoubtedly be accepted as authoritative. It has been compiled by authors who are clearly conversant with their subject, and this, together with the fact that much help has been given by specialists on various plant groups, will enable students of botany to consult it with confidence.

Chemistry.

Oxidation-Reduction Potentials. By Dr. L. Michaelis. Translated from the German Manuscript by Louis B. Flexner. (Monographs on Experimental Biology.) Pp. xii + 199. (Philadelphia and London: J. B. Lippincott Co., 1930.) 12*s.* 6*d.* net.

PROF. MICHAELIS's monograph is divided into two parts: in the first the theory of oxidation-reduction potentials is described, while the second is devoted to the physiologically important systems. The work may be considered the second volume of the author's "Hydrogen Ion Concentration", and the treatment stresses the relationship between oxidation-reduction potentials and hydrogen ion concentration. It provides a clearer and a thermodynamically

correct approach to cell energetics, and should lead to new investigations of the metabolism of the living cell. An oxidation is characterised by addition of oxygen or loss of hydrogen or loss of electrons, and a reduction by one of the converse processes.

In the first part, both inorganic and organic reversible oxidation-reduction systems are submitted to a mathematical exposition: in the second, the results are applied to sulphydryl and reversible respiratory systems of importance in biology; while the final chapter reviews the methods and results of measurements of the potentials in living cells. A bibliography is appended. The author does not claim an exhaustive treatment of the subject, since he does not consider our knowledge sufficiently advanced for a complete discussion of the physiological applications. The book gives an interesting and readable account of oxidation-reduction potentials, and should serve both to disseminate knowledge on the subject and to provide a stimulus to further research.

Lehrbuch der physikalischen Chemie. Von Prof. Dr. Karl Jellinek. Fünf Bände. Band 3: *Die Lehre von der statik homogener und heterogener Gasreaktionen.* Erste und zweite Auflage. Lieferung 8. Pp. 337-656. (Stuttgart: Ferdinand Enke, 1930.) 30 gold marks.

PHYSICAL chemists will welcome the appearance of a further portion of Prof. Jellinek's "Lehrbuch der physikalischen Chemie". Despite its somewhat misleading title, this part of Vol. 3 is chiefly concerned with equilibrium in liquid systems. About 30 pages are devoted to systems composed of non-electrolytes, and the remainder of the volume (270 pp.) deals with the properties of electrolytes in solution. The experimental methods for measuring conductivity, transport number, etc., are first described, followed by a thermodynamical discussion which includes a very complete account of activity coefficients and their determination. The volume concludes with an account of the modern kinetic theory of electrolytes as developed by Debye, Hückel, and Onsager. The whole is treated in the detailed and lucid manner which has characterised the earlier volumes of this valuable treatise.

Periodisches System: Geschichte und Theorie. Von Dr. Eugen Rabinowitsch und Dr. Erich Thilo. Pp. xii + 302. (Stuttgart: Ferdinand Enke, 1930.) 29 gold marks.

THIS book is essentially an essay on the periodic system from the point of view of modern physics. It opens with a historical account of the classification of elements; this is followed by an excellent description of the physicist's atom model, concluding with the Pauli principle and the allocation of electrons to the main and subsidiary energy levels of the atom. The evidence for the building up of the short and long periods is set out in detail and is illustrated by a large number of tables and diagrams of spectral terms. The properties of the elements and their principle compounds are then considered in the light of this physical evidence. Ionised compounds are of necessity discussed at greater length than covalent compounds, since the physical theory of the former type has proved to be more amenable to mathematical treatment.

Chemists in particular will be grateful to the authors for this useful and readable survey of the physical theory which underlies their science.

Electrical Engineering.

The Electrical Industry of Great Britain: Organization, Efficiency in Production and World Competitive Position. Pp. xvi + 233. (London: Beama Publication Department, 1929.) 42*s*. net.

THIS book has been prepared by the economic and statistical department of the British Electrical and Allied Manufacturers' Association; the statistical data given in it can therefore be trusted as approximately correct. It is very difficult to deduce rigorous conclusions from statistics, but some of the data given are instructive. It is interesting to note, for example, that the countries which exceed the 48 hour week convention are, in order of excess, Switzerland, Holland, Germany, and Hungary among European countries. Actually, 41·6 per cent of all Swiss employees are working in excess of 48 hours per week. Recent returns show that there are practically no unemployed in Switzerland during the summer months.

In Switzerland the 48 hour week can only be exceeded for economic reasons, such as for national security and for the countering of foreign competition at home. The result is that practically the entire Swiss engineering industry is now on the permissible maximum of 52 hours a week. Beyond 52 hours, overtime must be paid at the rate of 25 per cent extra, and not 50 per cent as in Great Britain.

Great Britain alone among the main competing countries is adhering to the exact letter of the 48 hour week. The authors consider that it would be inadvisable to advocate any reactionary move. They are in favour of establishing, with the help of cheap electricity from the grid, rural industries. They point out that in parts of Germany, particularly in Württemberg and the Black Forest, there has been a great industrial revival during the last five years, and that a large volume of applied art and furniture products are being exported from there to Great Britain.

Elektrische Gleichrichter und Ventile. Von Prof. Dr. A. Güntherschulze. Zweite erweiterte und verbesserte Auflage. Pp. iv + 330. (Berlin: Julius Springer, 1929.) 29 gold marks.

ELECTRICAL rectifiers and valves are used for converting alternating current into current which practically always pulsates in the same direction or into continuous direct current. This can be done in a great many ways, the most desirable in any given application depending on a great variety of circumstances.

In large power distributing schemes, rectifier sub-stations are used to replace small direct current generating stations. For broadcasting purposes there is a considerable demand for small rectifiers. Valves are also used for producing

high frequency current for laboratory use, for making cut-out switches, for producing alternating current having a special wave form, and for making measurements of very small alternating currents.

In the book under notice, mercury arc and mercury jet rectifiers are fully described. In addition we have good descriptions of contact, thermionic, electrolytic, and gas discharge rectifiers. In describing their action it is necessary to explain the many physical processes involved, and to get numerical relations advanced, mathematical theorems have to be employed. The author has done excellently in the space at his disposal, and the full bibliography given at the end of the book will be a great help to the researcher who wishes to probe more deeply into the subject. A list is also given of the patents which have been taken out for rectifiers, beginning with the aluminium condenser patented by Siemens and Halske in 1901.

The Theory of Electrical Artificial Lines and Filters. By A. C. Bartlett. Pp. ix + 155. (London: Chapman and Hall, Ltd., 1930.) 13*s.* 6*d.* net.

ALL engineers who are engaged in one or other of the numerous branches of electrical communication should know something of the theory of 'repeated' networks. These networks occur in artificial transmission lines, in line balances, in filters, and in phase shifters, all of which are of increasing practical importance. This book gives a very good account of the mathematical theory of these devices. Fifty years ago it was not uncommon for physicists to consider that the theory of numbers and subjects like determinants and continued fractions might well be omitted from a scientific or engineering curriculum. This book shows that it is lucky these ideas did not prevail. The theory of determinants --the author quotes Muir's "Theory of Determinants" as a book that should be consulted—is specially useful.

The generalised 'ladder artificial line section' is best solved by using continuants, a special form of determinants.

The methods of solving difference equations are also very useful in finding solutions of the physical problems involved in these networks. The author states that the literature of the subject is now so vast that he made no attempt to give a bibliography. From the engineer's point of view, however, it would have been helpful to give references to some of the classical papers.

Geology.

Geologisches Wanderbuch der westlichen Dolomiten. Von Dr. Maria M. Ogilvie Gordon. Pp. xv + 258 + 3 Tafeln. (Wien: G. Freytag und Berndt A.-G., 1928.) 15 gold marks.

DR. OGILVIE GORDON'S monumental treatise on the geology of the western Dolomites (see NATURE, vol. 121, p. 83; 1928) has been followed by the guide-book now under review. The region is famous for the beauty of its scenery, and is visited annually by many thousands of tourists; to the geologist it is of exceptional interest, as is evidenced by the numerous classical localities (St. Cassian, Heiligkreuz, the Marmolata, the Schlern, the Seiser Alpe, etc.) that lie within it. The picturesque jagged ridges and peaks and the elevated plateaux are formed by the various dolomitic stages of the Upper Trias, while the lower stages of the Trias and the underlying Permian may be well studied on the mountain sides. Other formations are of more restricted occurrence, but Jurassic rocks are found here and there, and the Neocomian beds of the Puez Alpe, in particular, are well worth a visit. The tectonics have not the bewildering complexity of many other Alpine regions, but nevertheless present many features of interest.

The first part of the book contains a useful summary of the stratigraphy and tectonics, and is illustrated by three plates of fossils. The area is then thoroughly explored in thirty-two excursions, each occupying a full day or rather less. Most of these follow the usual marked mountain tracks, and, if equipped with a large-scale topographical map, the geologist should have little difficulty in finding the way and in locating the exposures described. No particular experience in mountaineering appears to be called for except perhaps in the excursions to the Marmolata and the Sella group. Numerous vertical sections and excellent photographs illustrate the text, while the author's detailed geological map of the area between the Fassa and Gröden valleys is inserted in a pocket at the back of the book. The profuseness of its illustrations must be held responsible for the rather high price of this work. It will undoubtedly prove a most instructive and trustworthy guide to the geology of the region.

A Textbook of Geology. Part 1: *Physical Geology*, by Prof. Louis V. Pirsson; Part 2: *Historical Geology*, by Prof. Charles Schuchert. Part 1. Third edition, revised by Prof. William M. Agar, Prof. Alan M. Bateman, Prof. Carl O. Dunbar, Prof. Richard F. Flint, Prof. Adolph Knopf, Prof. Chester R. Longwell: revision edited by Prof. Chester R. Longwell. Pp. vii + 488. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1929.) 18*s.* 6*d.* net.

PIRSSON'S "Physical Geology" has deservedly been one of the most successful geological text-books during the last decade, although, like its many competitors, it had its weaknesses. Many of these are now removed from the very thoroughly revised edition that has recently appeared. The awkwardness of treatment involved by the former twofold division into dynamical and structural geology has been avoided by abandoning these divisions and changing the order of presentation. The treatment of stream erosion now emphasises the cycle of erosion for both humid and arid climates, and there is a new chapter on land forms in which the relations between landscape and geological structure are systematically and adequately dealt with. The chapter on volcanoes suffers from the absence of any reference to the work of Day, but is otherwise a well-written general account. The outer 2000-mile shell of the earth is regarded as 'solid', whereas the seismic evidence merely indicates that

it is rigid; there is no proof that it is crystalline below the crust. Isostasy is well treated, but recent work on near earthquakes and the crustal layers is not given. An up-to-date account of the structure of the Alps now appears. It is admitted that the cause of compressive deformation of the crust is one of the great mysteries of geology, and that it can at present be discussed only in a speculative way.

Many new illustrations have been added to the new edition, including admirable aeroplane photographs and block diagrams. Altogether the book is a well-balanced and effective presentation of a subject that is unusually difficult to deal with in an elementary way. Prof. Longwell and his collaborators have preserved the conservative spirit of the original text, clearly distinguishing between facts of observation and hypotheses of interpretation. The new edition should prove even more successful than the 1919 revision.

Structure and Surface: a Book of Field Geology. By C. Barrington Brown and F. Debenham. Pp. vii + 168. (London: Edward Arnold and Co., 1929.) 10*s.* 6*d.* net.

THIS admirable book has developed from an intention on the part of one of the authors to illustrate each of the simpler geological structures by an ideal block diagram and also by an actual example from an appropriate tract of the earth's surface. This enterprise has now been amplified by a text in which the structures and their recognition in the field are clearly discussed with special reference to the resulting land forms. The very numerous block diagrams, representing geological structures in three dimensions, are extremely effective, and give interest and vigour to a subject of which the treatment has often been woefully dull. To students of geology the book presents in a most attractive form the means of deducing from field observations many of the leading principles of structural geology and geomorphology, while for geography students it provides a sound basis for understanding intelligently the connexion between land forms and the rocks and structures out of which the surface relief has been carved. Two chapters are devoted to the construction of block diagrams, and notes on equipment and surveying instruments and field problems are added in three appendices. The book is one for which both students and teachers may well be grateful. Its production has clearly been a labour of love.

Mathematics.

Leçons sur quelques problèmes aux limites de la théorie des équations différentielles. Par Émile Picard. Rédigées par Marcel Brelot. (Cahiers scientifiques, Fascicule 5.) Pp. viii + 271. (Paris: Gauthier-Villars et Cie, 1930.) 60 francs.

IN continuation of Prof. Picard's course at the Sorbonne, this work is the third volume published in the 'Cahiers scientifiques' series. As would be expected from so distinguished an author, the book is a distinct mathematical contribution to both pure analysis and physics. The text is, for convenience, divided into two sections. The first, consisting of seven chapters, deals with ordinary differential equations which take their origin in mathematical physics. These equations in effect reduce to a study of the troublesome second order equation, and the author develops rigorously from both geometrical and analytical methods the powerful method of successive approximation. This involves an analytical consideration of the properties of certain functions, the conditions under which such functions exist in uniformly convergent series, and finally the theorem of Schmidt. The way is thus prepared for some important applications to the main problems of mathematical physics—the propagation of heat along a bar, vibrating strings, and the well-known problem of Fourier ("Œuvres", vol. 1, p. 85). The remaining chapters of Part I. are devoted to periodic integrals and infinite systems of linear algebraic equations which arise therefrom.

Part II. (Chaps. viii.-xii.) is concerned with partial differential equations. A consideration of harmonic functions, Dirichlet's problem, and the formulæ of Green and Poisson leads to a skilful extension of the contour method to that of a bounded surface. This yields greater generality in dealing with certain types of classical problems. Some instructive applications on the flow of heat in two dimensions and radiation in space are given. Finally, the equation of Fredholm and the potential functions of Laplace are studied together with some valuable deductions in analysis and physics.

The whole volume is most interesting and stimulating; it is undoubtedly a substantial contribution to the accessible literature on the theory of differential equations and their application.

The Theory of Approximation. By Prof. Dunham Jackson. (American Mathematical Society Colloquium Publications, Vol. 11.) Pp. viii + 178. (New York: American Mathematical Society, 1930.)

As the author of this work points out in his preface, "it is a brief essay in a field on which an encyclopædia might be written", namely, an investigation of the degree of approximation with which a continuous function can be represented by a polynomial of given degree.

Starting from the well-known theorems of Weierstrass on the approximate representation of a continuous function either by a polynomial or by a trigonometric sum, Prof. Jackson proceeds to prove other theorems on approximation by trigonometric sums, and then to examine the convergence of Fourier and Legendre series under the hypotheses of continuity over part of an interval, and of limited variation. Some generalisations of the principle of least squares are next discussed, and a very useful chapter follows on trigonometric interpolation in which some striking analogies between the theory of interpolation by means of trigonometric sums and by Fourier series are revealed. The interpolation formula analogous to the Féjer mean is especially interesting. In the final chapter is a very instructive introduction to the geometry of function space.

The book is excellently printed, and a welcome,

though somewhat rare, feature is the provision of an index of the principal theorems. This should prove a great advantage to the research student.

Cours d'analyse. (*Cours de l'École polytechnique.*) Par Prof. Paul Lévy. Tome 1. Pp. viii + 376. (Paris: Gauthier-Villars et Cie, 1930.) 120 francs.

This treatise is based primarily upon the course of analysis given by the author at l'École Polytechnique. It is divided into seven sections, each embracing from three to five chapters. The text covers the usual topics discussed in a modern study of continuous functions, namely, differential and integral calculus, theory of multiple integrals, geometrical applications of the calculus, and some elementary theory of differential equations.

Prof. Lévy has rightly insisted that the fundamental idea underlying an intelligent study of functions is the notion of growth in the value of a function and not mere formal calculus. The complete course is well planned and lucidly written, but the bulkiness of the volume renders it a little inconvenient to handle.

Miscellany.

The Drift of Civilization. By the Contributors to the fiftieth Anniversary Number of the *St. Louis Post-Dispatch*, including Charles G. Abbot, Richard E. Byrd, Albert Einstein, Guglielmo Ferrero, Sir Philip Gibbs, Maxim Gorky, Rudolf Maria Holzapfel, the Very Rev. Dean Inge, Count Hermann Keyserling, J. B. S. Haldane, Paul de Kruif, Stephen Leacock, Martin A. Nexö, Michael Pupin, James H. Robinson, Bertrand Russell, H. G. Wells. Pp. 254. (London: George Allen and Unwin, Ltd., 1930.) 7*s.* 6*d.* net.

Most thinking people at the present time busy themselves more with questions of the future than of the past. A popular series on 'To-day and To-morrow' sells its ten thousands, while manuals of history are left to the few. The volume before us, however, will not attain great success, nor is it of much value, because it is a collection of scraps, not co-ordinated in any way and not throwing any clear light on the question which its title suggests. There is a confused flicker like the varied lights of cars and bicycles and lorries on a wet road in the dark. But it is difficult to tell where they are all going, and some of them are obviously going in opposite directions. The communist Nexö, for example, tells us that food must be found for the starving proletariat, while J. B. S. Haldane remarks on the "general prosperity which has nearly banished underfeeding as a cause of ill-health". Both statements no doubt are true in their different connexions and with different applications. The reader is therefore left to find out for himself what is the general drift of civilisation from the disconnected views of the various eminent and interesting persons who have been got together by an enterprising American newspaper. It need scarcely be said that they all have a vivid vision of something, but in each case it is just the one thing that happens to interest the particular writer, and none of them has written at sufficient length even to develop his own thesis to a general conclusion.

One can therefore only sum up impressions and temperaments, and this would lead on the whole to an optimist view in a limited field. Great things are ahead of us: great things mainly in the realm of science, power over Nature, and increased enjoyment for the masses. None of the writers speaks of any growth in spiritual depth or beauty, or of any spread of peace and quiet happiness in the world. The only one who deals at all with this side of the future—the Dean of St. Paul's—looks for another form of Protestantism as the religion of the future. The men of science, as one might expect, are the most definite and constructive; for the rest, the book ends, as it began, with a note of interrogation.

F. S. M.

British Museum (Natural History), Cromwell Road, London, S.W.: General Library. Place-numbers of the Societies and other Corporate Bodies issuing Serial Publications, and of the Independent Periodical Publications, with Alphabetical Indexes. Second edition. Pp. v + 175. (London: British Museum (Natural History), 1930.) 5*s.*

Shelf lists of libraries possess a peculiar fascination for bibliographers, for the shelf list is the true catalogue of a collection. If its entries are sufficiently full, the student commands with its aid a complete bird's-eye view of a collection with a definite guide to the location of each unit. It represents all that an atlas is to the geographer or a directory to the local resident.

The present list, however, is not altogether a shelf list, though it closely resembles the shelf list type. It shows the order in which independent periodicals and institutions publishing one or more serial publications are arranged on the shelves with their distinctive call-numbers. Thus S 2418 = The United States Department of Agriculture, and S 2426 = The Smithsonian Institution. The information given, it will be noted, does not tell us whether the library possesses complete sets of the serial publications of the above bodies, or merely a selection of their publications relating more or less to natural science. The list is arranged upon geographical principles, the periodical publications of a region being grouped under the names of towns. The geographical arrangement has some administrative advantages, but for a research department classification by subjects is to be preferred.

The library appears to possess a fairly complete collection of the publications of British local natural history societies, but in specific branches of natural science, for example, botany, entomology, fish and fish culture, etc., it is singularly weak. One judges that the library serials are recruited mainly by exchange or gift, and that adequate funds for the purchase of serials are not available. If this is the case, it is to be hoped that the library will receive in future more generous treatment. Some of the deficiencies in its serial collection might be made good by judicious exchange with other

libraries—if exchange is permitted—for the present list shows that the library contains many serials which have no biological significance.

Eleutheros, or the Future of the Public Schools: a Desultory Dialogue. By J. F. Roxburgh. (To-day and To-morrow Series.) Pp. 94. (London: Kegan Paul and Co., Ltd., 1930.) 2*s*. 6*d*. net.

FOR several decades, educational reform has made enormous strides, with the result that the old established public schools of Britain have had their full share of the spotlight. The same era has seen many profound changes in these schools. Dr. Roxburgh, himself the headmaster of one of our public schools, has emphasised the aims of public school education in a remarkable manner. He has followed this up by defending these endeavours, and finally attempted to prove that such schools are the best.

Any attempt to criticise Dr. Roxburgh's efforts might leave an erroneous impression of the critic's bias against the methods which exist in our public schools. This would be unfortunate, for, whatever views the educationist may hold of the value of a public school education, he must agree that, in these days of uniformity and communism of method, it is refreshing to see that the public schools, in their independence, retain their personality and individuality. The author makes much of this point. However, one can neither dogmatise nor generalise in education. Wide views must be taken, and here the book is at fault, for a very narrow view of the subject has been assumed. To state, as the author does, that men who never went to anything but an elementary school were therefore never educated after fourteen, is a grave injustice to our State education.

We may or we may not agree with the tenets propounded in the book; but it is well worth reading, for the author has adopted the age-old dialogue style. This, at any rate, enables us to maintain an interrogative interest, thus continually asking ourselves, 'Are we agreed?'

Romance of the Machine. By Michael Pupin. Pp. v+111. (New York and London: Charles Scribner's Sons, 1930.) 4*s*. 6*d*. net.

MORE than fifty years ago, Prof. Pupin arrived in New York from Serbia, a mere boy unacquainted with the English language and almost penniless; to-day he enjoys both wealth and distinction. Like thousands of others from the Old World, he found the United States to be the land of opportunities of which he was not slow to take advantage. Supporting himself by lessons in wrestling and boxing, he entered on a course of study which ultimately led him to a chair in Columbia University. With teaching he combined invention, and he is known for one of the greatest improvements in telephony.

With Prof. Pupin's success has come an unfailing admiration for the constitution and ideals of the country of his adoption, and in the little book under notice he takes up the cudgels against the critics of 'machine civilisation'; endeavours to show how the telegraph, the telephone, broadcasting, and the automobile have assisted in the "Consolidation of the Union"; and tells us something of the telephone industry, "the largest and most perfectly co-ordinated industrial organisation in the world". His picture of "the roads blocked for many miles", which "makes one believe that every family in New York has an automobile, and that they are all out for a pleasure drive", will not appeal to all alike, but we are at one with Prof. Pupin in his hope that the telephone, the telegraph, the vacuum-tube oscillator, and the aeroplane "will aid in the art of cultivating international friendships". As for America's share in discovery, we like to recall Lord Playfair's remark that "science has no country though its investigators have birthplaces".

A Hundred Years of Publishing: being the Story of Chapman and Hall, Ltd. By Arthur Waugh. Pp. xvii+326+50 plates. (London: Chapman and Hall, Ltd., 1930.) 15*s*. net.

DICKENS, Trollope, and Carlyle, with Meredith figuring both as client of and reader to the house of Chapman and Hall—these are the names which will attract lovers of books to this work. The story of Dickens's relations with his publishers and of his love of gain at a time when he was in comfortable circumstances is a painful one. Mr. Waugh's narrative, however, is written in a large spirit of charity and forbearance towards all who served the firm whether as clients, clerks, readers, or managers.

The work, which is well illustrated with portraits and facsimiles, is not a mere chronicle of the output and fortunes of the firm. It is relieved by disquisitions on the successive changes which have taken place in the book trade from the time when publisher and bookseller were one down to present-day conditions. Within this period revolutionary changes have taken place, and the organisation of the publishing trade has become more complex and its business more speculative. The costs of publication have materially increased, and these costs cannot in all cases be passed on to the public in the shape of correspondingly enhanced prices. The chapters dealing with the new phases of publishing and book distribution are based upon competent authorities and add considerably to the value of the book. The work will be read with interest, and should find a permanent place upon the shelves of all concerned in the history of book production.

A Bibliography of Persia. By Lieut.-Col. Sir Arnold Wilson. Pp. x+253. (Oxford: Clarendon Press; London: Oxford University Press, 1930.) 20*s*. net.

WHEN Lord Curzon published his classical volumes upon "Persia and the Persian Question", it was his intention to add a third volume dealing with the bibliography of works about that country, but for obvious reasons this intention was never carried out. Sir Arnold Wilson has now partly supplied the desideratum by assembling in aphabetical order the names of the authors of some 6500 titles, including translations in European languages of original

Persian books and writings. From among this great mass of material the scientific specialist may pick out many details of special interest to himself, whether relating to such topics as the geology of oil-fields or local flora or to other matters, but his labour will be great until the work is completed by the addition of an analytical subject index. Among omissions we note the very informative "Quarterly Papers" of the 'Archbishop's Mission to the Assyrian Christians' at Urmi that were issued from 1890 until 1910; also R. Levy's "Bustan" and others. It would be helpful if well-known guide-books such as Murray's Handbook to Persia were entered under the name of the publisher as well as under that of the less familiar author. A brief chronological list of survey maps would also be a most useful addition. R. T. G.

Paint, Powder and Patches: a Handbook of Make-up for Stage and Carnival. By H. Stanley Redgrove and Gilbert A. Foan. Pp. xi + 170 + 16 plates. (London: William Heinemann (Medical Books), Ltd., 1930.) 7*s*. 6*d*. net.

THIS book gives a detailed and practical account of the art of 'making-up', both as regards the materials and technique. The authors claim that it is the first of its kind in which the subject is treated in a complete manner. Although addressed mainly to hairdressers who wish to become experts in the art of making-up, it will, as the authors point out, prove very useful to amateurs in theatrical performances, and many teachers may find it useful from this point of view. It is well written and illustrated, and gives a very large amount of information in a small compass.

Physics.

Magnetism. By Dr. Edmund C. Stoner. (Methuen's Monographs on Physical Subjects.) Pp. vii + 117. (London: Methuen and Co., Ltd., 1930.) 2*s*. 6*d*. net.

THE present work is one of a series of monographs which will be very useful in the library of every physicist. It is almost impossible for any scientific worker to keep pace with the advance of any subject, even though it may be quite closely cognate with what he is himself working at. To read all the published work in the proper critical spirit would involve the same sort of trouble as that of the historian who in writing a universal history took a year to write the history of a day. The present little book will do much to remove this difficulty. It assumes a good deal of knowledge of magnetism, but concedes that the knowledge may be a little rusty, and sets to work to supply all the latest information, treating it in a sound critical spirit and not merely as a catalogue of publications. For example, anyone who studied the same author's larger work, when it appeared four years ago, will be able to understand the great changes that have supervened, and also to learn what parts of the subject are still unsatisfactory.

The book is in five chapters, and in each of them there is something new to say. The first summarises the work, old and new, of the type of the celebrated experiment of Stern and Gerlach. The second and third deal with dia- and para-magnetism respectively. The experiments measuring the exceedingly small susceptibilities of most substances are very difficult indeed, and there is still much discrepancy between different experimenters; consequently, the theorists have often had the comparatively easy task of calculating their constants only to an order of magnitude, since it is usually possible to find some experiment to support the values obtained. If the experimental values could all be known with confidence, it would not only be a good discipline for the theorists, but would also probably enable them to advance the theory of the solid state. The fourth chapter deals with ferromagnetism, the theory of which has been revolutionised by Heisenberg. There is a short sketch of his theory, but it was found too difficult to give its detail in the compass of the book; to do so would have required a complete account of the new quantum theory. The fifth chapter includes, among other matters, an account of Kapitza's work on electric conductivity. Altogether, it will be seen that it is a most useful book, not only to the researcher but also to the advanced student.

Der Ramaneffekt. Von Prof. Dr. Clemens Schaefer und Dr. Frank Matossi. (Fortschritte der Chemie, Physik und physikalischen Chemie, herausgegeben von Prof. Dr. A. Eucken, Band 20, Heft 6.) Pp. iii + 52. (Berlin: Gebrüder Borntraeger, 1930.) 8 gold marks.

THIS excellent summary begins with a general account of the Raman effect, in which its relationship to other similar effects is carefully considered. The theory is treated first classically, when it is shown that, in addition to the Tyndall and Raman effects, scatterings of higher order are to be expected, and the point is stressed that asymmetrical forces are required for the Raman effect to appear. The theory is then given in terms of wave mechanics, and correspondences between the two methods of treatment are pointed out. The experimental technique, the polarisation of the lines, their intensities, and the effect of temperature variation on them, are only briefly described.

Considering the small space available, the discussion of results is comprehensive. The rotational levels in gases, with special reference to the selection rules, the scattering by water in its different states, the broadening of lines scattered in liquids, and the continuous spectrum appearing in certain liquids are all discussed. Organic substances are treated separately, and examples are given of the internal and external vibrations associated with certain radicals. The non-appearance of Raman lines in the scattering by ionic lattice crystals such as rocksalt, and their appearance when the crystals have polyatomic ions as in the carbonates and sulphates, is also discussed. The appearance of inactive frequencies in great strength is mentioned, and the case of calcite is discussed in detail.

An important omission in such a survey of a rapidly developing subject is the exact date up to which material has been included. From the non-inclusion of a reference to the scattering by powdered crystals, it may be judged that this survey was concluded about September 1929.

A. C. MENZIES.

Grenz Ray Therapy. By Dr. Gustav Bucky. With Contributions by Dr. Otto Glasser and Dr. Olga Becker-Manheimer. Translated by Dr. Walter James Highman. Pp. xii + 170. (New York: The Macmillan Company, 1929.) 15*s.* net.

GRENZ ray therapy means the treatment of disease with X-rays having wave-lengths of from 1 to 3 angstroms. It was inevitable that someone should seek to give a name to the region of the spectrum occupied by long wave-length X-rays. The question is sometimes put: "Where do ultra-violet rays leave off and X-rays begin?" The term 'grenz' used to describe this portion of the electromagnetic spectrum has been suggested by Dr. Bucky. Long wave-length X-rays would seem a preferable term, as the rays are considerably longer than those used in X-ray diagnosis and therapy at the present time, especially as only an imaginary boundary separates the ultra-violet from the X-ray spectrum.

An interesting section on the physics of these rays is contributed by Dr. Otto Glasser. The remainder of the book deals with attempts that have been made by Dr. Bucky and others to use these very easily absorbed rays in the treatment of disease. They are easily absorbed by any kind of tissue. One of the greatest difficulties of their therapeutic application undoubtedly lies in their means of production. These difficulties have, however, largely been surmounted now, and there is less danger of the accidental production of more penetrating rays than is desirable. We gather from the text that there has been considerable controversy among radiologists as to the advantages of treating skin conditions with these easily absorbed rays.

A Text-Book of Illumination. By Prof. William Kunerth. Pp. x + 269. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1929.) 15*s.* net.

THIS book is intended as a text-book in illumination mainly for senior electrical engineers studying at a university. Two-thirds of the book is devoted to the theoretical aspects of the subject and the rest to short chapters dealing with general principles affecting the application of illumination to special problems. There is also a short account of twenty-four laboratory experiments involving the use of photometric apparatus and the usual photometric calculations. Some of the experiments are designed to illustrate various visual phenomena encountered in the study of illuminating engineering.

The subject matter of the book is well chosen, and it is desirable that all illuminating engineers should receive instruction somewhat on the lines indicated by the author. Indeed, a strong case could be made out for the inclusion of such a course in the training of all electrical engineers. Unfortunately, the author's treatment of the subject is not all that could be desired. The book is not free from errors of fact, and quite a number of arguments are developed in a loose and confused manner.

The Physics of X-ray Therapy. By W. V. Mayneord. Pp. viii + 177. (London: J. and A. Churchill, 1929.) 10*s.* 6*d.*

THIS is, we believe, the first book by an English author on the physics of X-ray therapy, and Mr. Mayneord, who is physicist to the Radio-Therapeutic Department of the Cancer Hospital, London, has written a book which cannot fail to be of the greatest value to medical radiologists. Three-quarters of the book is devoted to the physical properties of X-rays, their penetration of and absorption by matter, their quantitative measurement, and their means of production. The remainder of the book is devoted to a résumé of factors affecting the choice of therapeutic conditions. The author is fully alive to the fact that what is physically best is often clinically impossible. He has nevertheless shown how to make the best of necessary compromise in these matters. The information in this book has been very well selected for the particular aim that the author has had in view. Mathematical treatment is almost eliminated, so that there need be no hesitation on the part of medical readers in making use of this very valuable book.

Physiology and Anatomy.

Recent Advances in Physiology. By Prof. C. Lovatt Evans. (The Recent Advances Series.) Fourth edition. Pp. xii + 446. (London: J. and A. Churchill, 1930.) 12*s.* 6*d.*

THE new edition of "Recent Advances in Physiology" well maintains the high standard set in its three predecessors. The whole book has been carefully revised, and two chapters are entirely new. These are of great importance. The first deals with the coronary circulation; the author briefly explains the experiments which have been carried out by physiologists, particularly Anrep and his collaborators, to determine the controlling factors of this circulation, and shows that these are, in order of importance, the arterial blood-pressure, chemical changes in the blood, and reflex control by the nervous system. In the second chapter the student is reminded of the long-accepted theory that pressure high up in the neck causes slowing of the heart by stimulation of the vagus. He now learns that this cardiac slowing is due to a remarkable reflex initiated in the dilatation at the root of the internal carotid artery, known as the carotid sinus. This reflex has been closely studied by the experimental method, and Prof. Lovatt Evans points out its importance in the regulation of blood-pressure when affected by such changes as severe hæmorrhage and alteration in posture.

The rapid advance of physiological science makes it inevitable that what was new in 1925 must now

be relatively old, but our one regret must be that some subjects previously discussed have to be omitted to make room for others. So valuable is every chapter in this edition that we hope to see them all included in the next, even if limited space compels some abbreviation.

The Mechanism of the Larynx. By V. E. Negus. Pp. xxx + 528. (London: William Heinemann (Medical Books), Ltd., 1929.) 45*s*. net.

MR. NEGUS presents here the results of his extensive inquiries into the form and function of the larynx. They range over the vertebrate kingdom from *Lepidosiren paradoxa* to man, and no detail of the structure of the forms examined seems to have escaped from thorough and fruitful consideration. The work is elaborate and, as a sustained effort in comparative anatomy and physiology applied to a field which is restricted but of wide interest, exemplary. In an introduction of great generosity and good humour, Sir Arthur Keith remarks that the author has the same patient power of assembling observation as Darwin had, and the same hot pursuit of function as urged John Hunter in all his quests. If these comparisons should induce a certain negativism in the attitude of some readers, the book will dispel it. Of nearly 500 pages of reading matter, there are few which do not serve as a vehicle for some point of interest, and, if the general reader were forearmed with such a knowledge of laryngeal structure as may be obtained from an hour's dissection and ten minutes' reading, he would find this work of science more interesting than most books about science. For the specialist it will endure as a major treatise. It includes under one cover as large, if not a larger body of facts than the usual specialist compilation, but in addition it casts fresh light upon problems too numerous to particularise in a short notice.

The Mycoses of the Spleen. By Dr. Alexander George Gibson. (The Anglo-French Library of Medical and Biological Science.) Pp. xii + 169 + 10 plates. (London: Kegan Paul and Co., Ltd., 1930.) 12*s*. 6*d*. net.

IN this book Dr. A. G. Gibson has amplified the suggestion he put forward in 1913, that certain forms of splenomegaly were due to a streptothrix organism invading the spleen. His examination of many spleens has convinced him that the threads generally considered to be altered tissue fibres are mainly mycelial fibres, and he regards these as the causal organism of acholuric jaundice and the group of conditions known as splenic anæmia. The evidence for his conclusions is clearly described and well illustrated. The investigations of other workers who have found similar organisms are reviewed, and various criticisms are considered. Although Dr. Gibson puts forward a strong case and is convinced that his views are correct, he does not in any way regard this etiological problem as solved. He indicates a line of study requiring wider investigation, and is content to wait until results shall be general and uniform before considering his theory to be proved.

The Science of Voice: a Book on the Singing and Speaking Voice based upon the latest Research in Physics and Physiology, with advice to those interested in Talking Movies and other Mechanical Reproducing Devices. By Douglas Stanley. Pp. vi + 327. (New York, Boston and Chicago: Carl Fischer, Inc., 1929.)

IN this book the scientific aspects of voice receive much more elementary treatment than in the works of Fletcher or Paget. A considerable portion of the volume is devoted to the musical uses of voice, and the attempts made at their definition in physical terms are of interest. In the chapter dealing with researches upon breath expulsion one would have expected to find a careful discussion of the influence of the resonances of the apparatus, which is described as consisting of a French gas mask strapped tightly over the singer's face and connected by a large rubber tube to an air-tight box inverted in a tank of water. Such a system having resonances within the range of the singing voice would unduly facilitate the production of certain notes The third section of the book, devoted to interpretation and musicianship, might provide useful material for the psychologist.

Bainbridge and Menzies' Essentials of Physiology. Sixth edition, edited and revised by Prof. H. Hartridge. Pp. xii + 497 + 30. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1929.) 14*s*. net.

THIS is a most popular manual with junior students and is very widely used by them in preparation for examinations. The earlier editions were framed on the plan of Starling's excellent text-book of physiology and constituted readable and connected summaries of the latter, which the beginner found rather formidable. Emanating in the first instance from St. Bartholomew's Medical School, this little text-book has undergone improvement under the successive heads of physiology. The present edition has been subjected to drastic revision, with a resulting improvement which places it as the most up-to-date manual now at the disposal of students.

Psychology and Philosophy.

John Dewey, the Man and his Philosophy: Addresses delivered in New York in celebration of his Seventieth Birthday. Pp. vii + 181. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1930.) 10*s*. 6*d*. net.

THIRTY years ago, the young American who wanted to pursue the higher learning was apt to betake himself to a German university for three or four years. But, independently of the changes brought about by the War, that custom has become greatly modified. If he comes to Europe at all, he is more likely to stay only one year, and it is not a foregone conclusion that the year is spent in Germany. The fact is that America has been growing her own science and her own philosophy. In philosophy she had, following the European model, her school

of neo-Hegelians, represented by such a man as W. T. Harris. But she seems to have cast aside the *-isms* of the Old World, and to have excogitated a philosophy more in keeping with her own genius and her own outlook. The names of William James and John Dewey stand out in this connexion as names of which any nation might well be proud. Through them the influence of American thought is being felt to the ends of the earth. James died young, but Dewey is happily still with us. He passed his seventieth birthday in October last, and the occasion was marked by a celebration in which some of the foremost of American thinkers took part. This book places on record what was said on that occasion. The speeches constitute a worthy tribute to a very distinguished man; and we may add, for the benefit of people who have not read Dewey, that a good general idea of what has been going on in recent years in philosophical and educational America may be gathered from a perusal of these speeches.

Psychologies of 1930. By Alfred Adler, Madison Bentley, Edwin G. Boring, G. S. Brett, Harvey Carr, John Dewey, Knight Dunlap, J. C. Flugel, Walter S. Hunter, Pierre Janet, Truman L. Kelley, K. Koffka, Wolfgang Köhler, K. N. Kornilov, William McDougall, John Paul Nafe, I. P. Pavlov, Friedrich Sander, A. L. Schniermann, C. Spearman, Leonard T. Troland, Margaret F. Washburn, Albert P. Weiss, Robert S. Woodworth. Edited by Carl Murchison. (The International University Series in Psychology.) Pp. xix+497. (Worcester, Mass.: Clark University Press; London: Oxford University Press, 1930.) 27*s*. net.

THE editor of this volume is to be congratulated heartily upon having brought about a sort of quinquennial stock-taking of psychologies. A comparison of this collection of papers with that which appeared in 1925 shows fairly clearly the changes of attitude and conviction which have meantime taken place.

To the interested onlooker the conflict between the rival schools of psychology has its amusing as well as its edifying aspect. According to the tradition in which most of us were reared, psychology is the science of the mental life, and ascertains its facts by the method of introspection. According to the behaviourist school, which is strong in the United States, a study so pursued is no science at all, since science truly so called is conversant only with the objective facts, which in this case are the facts of human behaviour. So the behaviourist can make no terms with introspection. Similarly, as Prof. Spearman points out in his spirited contribution, the Berlin 'gestaltists' 'throw cold water' upon refined analysis; the structuralists would have the problems of function indefinitely postponed; and the functionalists think 'very small beer' of the structuralists. For his part, Prof. Spearman, who curiously labels himself a factorist, regards his school as a school to end schools, the destined healer of all these unhappy divisions.

Prof. McDougall indicates his position by an advance from the 'purposive' psychology of 1925 to the 'hormic' psychology of 1930. This volume also gives, for the first time in the English language, an account of the three leading Russian psychologies. Prof. Murchison claims that psychology is rapidly coming of age. The more controversial papers in this collection rather suggest that psychology is still suffering from growing pains.

The Creed of a Biologist: a Biologic Philosophy of Life. By Prof. A. S. Warthin. Pp. viii+62. (London: Constable and Co., Ltd., 1930.) 7*s*. 6*d*. net.

IN this little book, Prof. Warthin has put forward an argument in favour of a completely scientific basis of life. Yet, with scientific knowledge in its present state, this propounded philosophy appears to contain as much untrustworthy dogma as is commonly associated with religion. That there is no proof of an anthropomorphic deity and that life is governed completely by scientific law are two maxims which the author accepts without reserve. Yet there are still many cloaks of mystery, and where we have religious faith, we also have scientific hypothesis.

The chief principle of Prof. Warthin's creed is that the complete aim of life is evolutionary immortality. One assumes, therefore, that he believes in ontogenetic mortality but phylogenetic immortality; the latter being made possible by the continuity of the germ plasm. Such is his biological creed. What it is, and how one should behave in order to conform to its doctrines, are well worth reading. The book will meet with supporters and dissenters, and therein lies its value to intellectual thought.

Forthcoming Books of Science.

Agriculture, Forestry, and Horticulture.

Macmillan and Co., Ltd.—The Student's Flora of the British Islands, Sir J. D. Hooker. Re-issue; Hortus: a Concise Dictionary of Gardening, Dr. L. H. Bailey.

Anthropology and Archæology.

Allen and Unwin, Ltd.—The Evolution of the ... F. Müller-Lyer. Translated by F. W. Stella ... *ridge University Press.*—How it Happened, Rhoda Power; The Bronze Age, Prof. V. Gordon Childe. *G. G. Harrap and Co., Ltd.*—Folk-Tales of all Nations. Edited by F. H. Lee. *Methuen and Co., Ltd.*—A History of the Vikings, T. D. Kendrick; A Season's Work at Ur: Being an Account of the British Museum Archæological Mission to Babylonia, 1919, Dr. H. R. Hall. *Oxford University Press.*—Nuer Customs and Folklore, R. Huffman; Mesopotamian Origins, E. A. Speiser; Clay Figurines of Babylonia and Assyria, E. D. van Buren. *G. Routledge and Kegan Paul, Ltd.*—The History of World Civilization, from Prehistoric Times to the Middle Ages, Prof. H. Schneider.

2 vols.; A History of Modern Culture, 1543–1687, Prof. P. Smith; Wit and Wisdom in Morocco: a Study of Native Proverbs, Dr. E. A. Westermarck; A Sudanese Kingdom: an Ethnological Study of the Jukun-Speaking Peoples of Nigeria, C. K. Meek; Matriarchy in the Malay Peninsula and Neighbouring Countries, G. A. de C. de Moubray; The Mongol in our Midst: a study of Man and his Three Faces, Dr. F. G. Crookshank. New edition. *H. F. and G. Witherby.*—The Origin of the Human Skeleton: An Introduction to Human Osteology, Dr. R. Broom; The Formenkreis Theory and the Progress of the Organic World, Dr. O. Kleinschmidt. Translated by the Rev. F. C. R. Jourdain.

Biology.

George Allen and Unwin, Ltd.—Human Heredity, Bauer-Fischer-Lenz. Translated by Eden and Cedar Paul. *Edward Arnold and Co.*—Philosophy of a Biologist, Sir Leonard Hill; Hill Birds of Scotland, Seton Gordon. Popular edition; Environment and Plant Development, Prof. H. Lundegardh. Translated by E. Ashby, with notes and adaptations to British conditions. *Cambridge University Press.*—Agricultural Entomology, Kenneth Smith; Mendel's Principles of Heredity, the late Dr. W. Bateson. *Cassell and Co., Ltd.* -The Science of Life, H. G. Wells, Prof. J. S. Huxley, and G. P. Wells. *J. and A. Churchill.* —Recent Advances in Entomology, Dr. A. D. Imms. *Gurney and Jackson.*—Game Animals of the Sudan: their Habits and Distribution, Capt. H. C. Brocklehurst. *Crosby Lockwood and Son.*—Birds of Nyasaland, C. F. Belcher. *Oliver and Boyd.*—The Migration of Butterflies, C. B. Williams. *Oxford University Press.*—The Interpretation of Development and Heredity: a Study in Biological Method, Dr. E. S. Russell; The Evolution of Biology, Dr. C. Singer; Index Londinensis. An emended and enlarged edition continued up to the End of the Year 1920 of Pritzel's Alphabetical Register of Representations of Flowering Plants and Ferns. Prepared for the Royal Horticultural Society of London by Dr. O. Stapf. Vol. IV. (Kadsura-Pedicellia); Early Theories of Sexual Generation, Prof. F. J. Cole; A Manual of Practical Vertebrate Morphology, J. T. Saunders and S. M. Manton; Sea Angling Fishes of the Cape (South Africa). A Natural History of some of the Principal Fishes caught by Sea Anglers and Professional Fishermen in Cape Waters, C. L. Biden; Plants of the Gold Coast, F. R. Irvine; The Woad Plant and its Dye, Dr. J. B. Hurry. *G. Routledge and Kegan Paul, Ltd.*—The Nature of Biology, Prof. L. Hogben. *Seeley, Service and Co., Ltd.*—The Life of the Sea Trout, especially in Scottish Waters. With chapters on Reading and Measuring Scales, G. H. Nall. *Sidgwick and Jackson, Ltd.*—The Biology of Mammals, Prof. J. Ritchie; A Second Biology, Prof. S. Mangham and Prof. W. R. Sherriffs (Biological Handbooks); The Principles of Animal Genetics, E. B. Ford; Experimental Zoology, Prof. J. S. Huxley; Animal Morphology, Prof. W. Garstang (Text-books of Animal Biology). *University of London Press, Ltd.*—General Elementary Biology, Lucy E. Cox and Mary E. Phillips; A Four Years' Course in Nature Study for Junior Schools, Elsie V. M. Knight. *H. F. and G. Witherby.*—A History of the Birds of Norfolk, B. B. Riviere.

Chemistry.

G. Bell and Sons, Ltd.—The Chemical Investigation of Plants, Dr. L. Rosenthaler. Translated by Dr. Sudhamoy Ghosh. *J. and A. Churchill.*—Recent Advances in Analytical Chemistry. Edited by Dr. C. A. Mitchell. 2 vols. *Constable and Co., Ltd.*—Quantum Chemistry: a Short Introduction in Four Non-Mathematical Lectures, Dr. A. Haas. Translated by L. W. Codd. *Longmans and Co., Ltd.* —Enzymes, Prof. J. B. S. Haldane; Recent Advances in Physical and Inorganic Chemistry, Prof. A. W. Stewart. New edition. *Macmillan and Co., Ltd.*—A School Course of Chemistry, Prof. J. R. Partington. *Methuen and Co., Ltd.*—Practical Physical Chemistry, Prof. K. Fajans and J. Wüst. Translated by B. Topley, with an Introduction by Prof. F. G. Donnan; The Electrochemistry of Solutions, Dr. S. Glasstone; Natural Terpenes, Dr. J. W. Baker; Photochemistry, Dr. D. W. G. Style. *Oxford University Press.*—Chemistry, Dr. E. J. Holmyard. (Makers of Science Series.) *G. Routledge and Kegan Paul, Ltd.*—The Materials of Life: a General Presentation of Biochemistry, T. R. Parsons. *University of London Press, Ltd.*—A First Chemistry for Schools, A. Brooks.

Engineering.

Edward Arnold and Co.—Hydraulics, Prof. F. C. Lea. New edition. *Ernest Benn, Ltd.*—The General Principles of Chemical Engineering, S. G. M. Ure; The Mechanical Principles of Mining Appliances, Prof. H. Louis; Mineral Deposits, Prof. H. Louis; Coal-cutting Machinery and its Applications, S. Mavor; Haulage and Winding, Prof. G. Poole; Motive Power and the Modern Steam Turbine, Sir Charles Parsons and R. Dawson; Insulated Electric Cables, C. J. Beaver. Part 2: Manufacture and Testing. Part 3: Installation; Electrical Measuring Instruments, Dr. C. V. Drysdale and A. C. Jolley. Part 3: Steady Current Laboratory Instruments; Part 4: Alternating Current Laboratory Instruments; Rotary Convertors, F. P. Whitaker. *Chapman and Hall, Ltd.*—Testing Radio Sets, J. H. Reyner; Charts and Notes on Marine Boiler Design, H. C. Walker; Switchgear Practice, H. E. Poole; Electrical Engineering Practice, J. W. Meares and R. E. Neale. Vol. 3. New edition. *Crosby Lockwood and Son.* —Modern Workshop Practice, E. Pull. New edition; Marine Aircraft: Elementary Naval Architecture, Capt. P. H. Sumner; Punches, Dies, and Tools for Manufacturing in Presses, J. V. Woodworth. New edition; Naval Architect's and Shipbuilder's Pocket-Book of Formulæ, Rules, and Tables, and Marine Engineer's and Surveyor's Handy Book of Reference, C. Mackrow. New edition, revised by L. Woollard; Boiler House Manual, B. Frisby; Gas Installations and Appliances, A. T. Gilbert; Purification and Disposal of Sewage, C. J. Nurse; Mechanical Handling and Storing of Material, G. F. Zimmer. With a Foreword by Sir John Purser Griffith. New edition; Chemical Engineering Applied to the Cement Rotary Kiln, Dr. G. Martin. *Longmans and Co., Ltd.*—Materials and Structures, Dr. E. H. Salmon; Builders' Materials, R. F. B. Grundy. *Methuen and Co., Ltd.*—Electric Light and Power, E. E. Brooks and W. H. N. James. New edition.

Geography and Travel.

Cambridge University Press.—Great Britain: Essays in Regional Geography by twenty-six authors. Edited by A. G. Ogilvie, with an introduction by Sir E. J. Russell. Second edition; Lands of the Eastern Caliphate, G. Le Strange. New edition; Cambridge School Geographies, E. D. Laborde. Book 4: The British Empire. *Jonathan Cape, Ltd.*—Green Hell, J. Duguid. *Chapman and Hall, Ltd.*—Surveying for Schools, S. W. Perrott. *Constable and Co., Ltd.*—Arabian Peak and Desert, A. Rihani; Things Which are Seen, Prof. A. J. Toynbee. *Macmillan and Co., Ltd.*—The Records of the Hudson's Bay Company. Vol. 1: Journal of Occurrences in the Athabasca Department. Vol. 2: Documents Relating to the Organisation of the Trade. Vol. 3: Diary of Overland Journey from York Factory to the Pacific Coast; The Handbook of Tanganyika, 1930. General Editor, G. F. Sayers. *Methuen and Co., Ltd.*—Tudor Geography: 1485–1583, Prof. E. G. R. Taylor. *G. P. Putnam's Sons, Ltd.*—Nonsuch, Dr. W. Beebe; A Year on the Great Barrier Reef, Dr. C. M. Yonge; Little America, Rear-Admiral R. E. Byrd; N. by E., R. Kent; The Holy Cities of Arabia, E. Rutter. Popular edition; Hidden Wealth and Hiding People, M. Terry. *G. Routledge and Kegan Paul, Ltd.*—The Travels of Marco Polo. Translated into English from the text of L. F. Benedetto by Prof. A. Ricci. With and Introduction by Sir Denison Ross; The Travels of an Alchemist: the Journey of the Taoist Ch'ang Ch'un from China to the Hindukush at the summons of Chingiz Khan. Translated, with an Introduction, by A. Waley; Travels in India, Capt. B. Hall. Selected and edited with a Biographical Introduction, by Prof. H. G. Rawlinson. *Royal Geographical Society.*—The Record of the Royal Geographical Society, 1830–1930, Dr. H. R. Mill. *Seeley, Service and Co., Ltd.*—The Island Builders of the Pacific, Dr. W. G. Ivens.

Mathematical and Physical Sciences.

Edward Arnold and Co.—Lecture Experiments in Optics, B. K. Johnson. *G. Bell and Sons, Ltd.*—The Scattering of Light, Prof. Sir C. V. Raman. (International Text-Books of Exact Science); The Physics of High Pressure, Prof. P. W. Bridgman. (International Text-Books of Exact Science.) *Ernest Benn, Ltd.*—The Ether of Space, Sir Oliver Lodge. *A. and C. Black, Ltd.*—Deductive Geometry, R. W. M. Gibbs; Earth and Sky: a Brief Account of the Earth's Situation in Space, with Some Account of its Internal Structure, C. H. Dobinson. *Blackie and Son, Ltd.*—Applications of the Absolute Differential Calculus. Dr. A. J. M'Connell; The Physics of Solids and Fluids, with Recent Developments. Selected chapters from Müller-Pouillet's "Lehrbuch der Physik" (11th edition, 1929), Prof. P. P. Ewald, Prof. T. Pöschl, and Prof. L. Prandtl. Translated by W. M. Deans and Dr. J. Dougall. *Cambridge University Press.*—The Mysterious Universe, Sir James Jeans; The Theory of Ruled Surfaces, W. L. Edge; Geometry of Four Dimensions, Dr. A. R. Forsyth. Two volumes; Radiations from Radioactive Substances, Sir Ernest Rutherford, Dr. J. Chadwick, and C. D. Ellis; An Outline of Wave Mechanics, N. F. Mott; Principles and Practice of Geophysical Prospecting, Edited by A. Broughton Edge and Prof. T. H. Laby; The Mathematical Papers of Sir William Rowan Hamilton. Edited by Prof. A. W. Conway and Dr. J. L. Synge. Vol. 1: Geometrical Optics. *W. and R. Chambers, Ltd.*—Navigation, W. J. Caird and H. McCallum. New edition. *Chapman and Hall, Ltd.*—Electrolytic Conduction, Prof. F. H. Newman. *Macmillan and Co., Ltd.*—Standard Four-figure Mathematical Tables, Prof. L. M. Milne-Thomson and Dr. L. J. Comrie. Edition A: with Positive Characteristics in the Logarithms. Edition B: with Negative Characteristics in the Logarithms; Astronomy: an Introduction, Prof. R. H. Baker; Progressive Trigonometry, Part 2: Plane Trigonometry, F. G. W. Brown; Lectures on Theoretical Physics delivered at the University of Leiden, Prof. H. A. Lorentz. Translated by Dr. L. Silberstein and A. P. H. Trivelli. Vol. 3: The Principle of Relativity for Uniform Translations (Special Theory of Relativity). *Methuen and Co., Ltd.*—Theoretical Physics, Prof. W. Wilson. Vol. 1: The Quantum Theory, Prof. F. Reiche. Translated by H. S. Hatfield and H. L. Brose. New edition; The Applications of Interferometry, W. E. Williams; Tables of Physical Constants, Dr. W. H. J. Childs; Mine Atmospheres, Prof. I. C. F. Statham and W. Payman. *Oxford University Press.*—A Manual of Greek Mathematics, Sir Thomas L. Heath; An Introduction to the Theory of Functions of a Complex Variable (Taylor Series), P. Dienes; A Monograph of Viscometry, G. Barr; Slide Rule Calculations, H. O. Cooper.

Medical Science.

Cambridge University Press.—Health at the Gateway, E. W. Hope. *Jonathan Cape, Ltd.*—De Mortuis, C. MacLaurin. *Cassell and Co., Ltd.*—Radium-Therapy: Principles and Practice, G. E. Birkett. *J. and A. Churchill.*—Public Health Practice in the Tropics, Dr. J. B. Kirk; Human Physiology, Dr. F. R. Winton and Dr. L. E. Bayliss; Recent Advances in Psychopathology, Dr. M. Culpin; Recent Advances in Microscopy. Edited by Dr. A. Piney. *Constable and Co., Ltd.*—Social Control of the Mentally Deficient, Dr. S. P. Davies. *Longmans and Co., Ltd.*—The Physiology of Muscular Exercise, the late Prof. F. A. Bainbridge. New edition, rewritten by Dr. A. V. Bock and Dr. D. B. Dill. *Methuen and Co., Ltd.*—Manipulation as a Curative Factor: Osteopathy and Medicine, Dr. Ethel Mellor. *Oxford University Press.*—The History of Paediatrics: the Progress of the Study of Diseases of Children up to the end of the XVIIIth Century, G. F. Still. *G. Routledge and Kegan Paul, Ltd.*—The Principles of Epidemiology, Dr. C. O. Stallybrass. *Charles Scribner's Sons.*—Riders of the Plagues, J. A. Tobey.

Metallurgy.

Ernest Benn, Ltd.—Industrial Steel and Iron: their Constitution and Properties, P. Oberhoffer. Translated by W. Austin. *Chapman and Hall, Ltd.*—Non-Metallic Inclusions in Iron and Steel, Dr. C. Benedicks and H. Löfquist; Stainless Iron and Steel, J. H. G. Monypenny. New edition. *Crosby Lockwood and Son.*—Heat Treatment in Forging Steel, B. Saunders.

Meteorology.

John Murray.—Temperature Chart (Wall Diagram), T. Saunders. *Oxford University Press.*—Climate, W. G. Kendrew.

Miscellany.

Edward Arnold and Co.—The Indexing of Books, Dr. J. W. T. Walsh. *Gurney and Jackson.*—Memories of Four-Score Years Less Two, 1851–1929, Abel Chapman. With a Memoir by G. Bolam. *G. G. Harrap and Co., Ltd.*—Industrial Britain: A Survey, Dr. A. Wilmore. *John Murray.*—The Science of Marking, Dr. Terry Thomas. *G. Routledge and Kegan Paul, Ltd.*—Forged, Anonymous, and Suspect Documents, Capt. A. J. Quirke.

Philosophy and Psychology.

George Allen and Unwin, Ltd.—The Education of Children, Dr. A. Adler; The Religion of Man. Being the Hibbert Lectures for the Year 1930, Rabindranath Tagore; The Structure of Thought, L. Fischer. Translated by W. H. Johnston; Number: the Language of Science, Dr. T. Dantzig. *Edward Arnold and Co.*—The Animal Mind, Prof. C. Lloyd Morgan. *Hodder and Stoughton, Ltd.*—The Sub-normal School Child. Volume 2: The Backward Child, Prof. C. Burt. *Longmans and Co., Ltd.*—Social Psychology, Prof. E. T. Kreuger and Prof. W. C. Reckless; Child Psychology, Margaret W. Curti. *Macmillan and Co., Ltd.*—The Faith of a Moralist, Prof. A. E. Taylor. 2 vols. (Gifford Lectures, 1926–1928.) *Methuen and Co., Ltd.*—A Modern Introduction to Logic, L. Susan Stebbing; The Social Contract of the Universe, C. G. Stone; Lectures on Ethics, Immanuel Kant. Translated by L. Infield. With an Introduction by Prof. J. MacMurray; Psychology: a Study of Mental Life, Prof. R. S. Woodworth. New edition. *Oxford University Press.*—A History of Psychology in Autobiography. Vol. I. *G. Routledge and Kegan Paul, Ltd.*—Intellectual Growth in Young Children, Susan Isaacs. With two Appendices by N. Isaacs; The Concentric Method in the Diagnosis of Psychoneurotics, Prof. M. Laignel-Lavastine; The Psychology of Intelligence and Will, H. G. Wyatt; Integrative Psychology: a Study of Unit Response, W. M. Marston, C. D. King, and Elizabeth H. Marston. *Charles Scribner's Sons.*—The Dynamic Universe, Prof. J. Mackaye.

Technology.

Ernest Benn, Ltd.—The Chemistry and Manufacture of Pigments and Paints, C. A. Klein and W. G. Aston; Modern Brickmaking, A. B. Searle. New edition; The Chemistry and Physics of Clays and other Ceramic Materials, A. B. Searle. New edition; The History of the Gas Industry, W. T. Dunn; The Manufacture of Gas, H. Hollings and others; Gas Calorimetry, Major C. G. Hyde and F. E. Mills; The Chemistry and Technology of Artificial Silks, A. J. Hall. *Chapman and Hall, Ltd.*—Electro Deposition of Chromium, D. J. Macnaughton. *Crosby Lockwood and Son.*—Woodcraft Design and Construction, G. H. Barker; The Modern Soap and Detergent Industry. Second edition, revised by Dr. G. Martin. Vol. 1: Theory and Practice of Soapmaking.

Printed in Great Britain by R. & R. CLARK, LIMITED, *Edinburgh.*

retired on Aug. 1, 1912, having in 1911 been raised to the knighthood.

Long a member of the Institution of Naval Architects, Sir William Smith became a member of Council in 1887 and a vice-president in 1906. He undertook the design of the well-known Antarctic expedition ship *Discovery*; became vice-chairman of the Board of Trade Committee on the Load Line for Merchant Ships; for eight years was chairman of the Board of Studies in Civil and Mechanical Engineering for the University of London, and was also chairman of the Advisory Committee of the William Froude Experimental Tank at the National Physical Laboratory. He was also a member of the Technical Committee responsible for the restoration of H.M.S. *Victory*.

We regret to announce the following deaths:

Dr. Lewis Evans, founder of the Lewis Evans Collection of early scientific instruments at Oxford, on Sept. 25, aged seventy-seven years.

Mr. Daniel Guggenheim, an American financier and member of the mining firm of Guggenheim Brothers, who established in 1926 the Daniel Guggenheim Fund of £500,000 for the promotion of aviation, on Sept. 28, aged seventy-four years.

Sir Francis Watts, K.C.M.G., first principal of the Imperial College of Tropical Agriculture at Trinidad, on Sept. 26, aged seventy years.

News and Views.

There has recently been in progress at the Avonmouth Docks, Bristol, an experimental demonstration of the possibilities of a new system of hydro-electrical power development by means of the head due to the tides, which in the estuary of the Severn are of the order of 30-40 ft. Hitherto, the economical development of tidal power on commercial lines has been beset by the difficulty of obtaining uninterrupted functioning of the generating machine. The turbines, requiring a minimum head or pressure for working purposes in the neighbourhood of 10 ft., are necessarily inoperative during such times as the difference between the level of the impounded water and that in the outer channel is less than this. The periods are considerable and may absorb a third of the tidal time. The difficulty can be overcome by a complex system of auxiliary basins or reservoirs, but the cost of these is generally prohibitive. Under the new system, which is due to Mr. Paul Shishkoff and is being exploited by Hydro-Thermal Power Ltd., of Westminster, a portion of the power produced by the turbines under tidal action is converted into heat by means of a water friction brake, the heated water being stored under pressure in a steam accumulator. When the tidal head falls below the minimum required to drive the water turbine, power is generated by a turbo-alternator driven by steam from the accumulator. In this way the intermissions of tidal force are bridged over. The power system is, of course, of a dual nature, being partly by water and partly by steam, but it has the merit of being self-contained and is, indeed, quite simple in design. The experimental plant at Avonmouth is only of small calibre, with an ordinary continuous load of 16 kw. and a peak load of 32 kw., but its successful operation opens out a wide field of possible development for the Shishkoff system.

A very interesting and, it is hoped, a far-reaching development in the campaign against foot-and-mouth disease is indicated in an important new order issued by the Ministry of Agriculture under the Diseases of Animals Acts, making provision for the use of immune serum in the endeavour to check the spread of this most highly infectious and costly disease. The order provides that "The Minister may, for the purpose of preventing the spread of foot-and-mouth disease, treat with serum, as often as may be, in his opinion, necessary, any animals which may have been in contact with animals affected with foot-and-mouth disease or which have, in his opinion, been exposed to the danger of infection of that disease." This order marks a very big step forward, as it indicates strong reason to hope that one of the greatest difficulties hitherto met with in the spread of the disease and its control by serological methods has been overcome. That difficulty was due to the fact that there are several strains of the virus of foot-and-mouth disease, and hyper-immune serum found to be effective against one strain failed to produce any protection against the others. As the source of infection in Great Britain was varied, possibly European or even South American, serum proved to be effective in one case was quite useless in the next case. There are three known strains of virus, and the obvious aim has been to produce a serum effective against all three. It is believed that this has now been accomplished, and it is this trivalent serum that it is proposed to use. Fortunately it is being prepared on the Continent (Holland and Germany), so the establishment of an institute for its production, which would inevitably be a possible source of danger in Great Britain, will be unnecessary.

The passive immunity to foot-and-mouth disease produced by the new serum is only of ten days' duration, so the inoculation will probably have to be repeated once or twice in an outbreak. The slaughter policy of *affected animals* is not to be varied, for the serum is preventive, not curative, and it is essential that the animal producing virus be stamped out. There must be no possible risk of producing carriers. The great value of this new procedure will be that when an outbreak occurs animals in the vicinity can be immediately immunised, and it may be possible, if sufficient material is available, to establish an immune circle around the outbreak, and so enormously reduce the danger of its extension. Occasions have occurred in the past where most valuable animals have had to be destroyed, not because they were affected, but because they had been exposed to infection. It is to be hoped that, as the result of the new procedure, such animals may be saved.

Stockowners should be reassured that since the serum contains no living virus there can be no danger in its use. The order provides that the expenses incurred in its execution must be borne by the owner of the animals, and may be recovered summarily as a civil debt. The Ministry of Agriculture is to be congratulated on this forward step, and there is good reason to hope that it will be fully justified.

MR. WALTER GOODACRE, a past president of the British Astronomical Association and the director of its Lunar Section, recently gave the sum of £300 to the Association for the foundation of a medal and gift, to be awarded at intervals of a few years to a member of the Association, selected by the Council, in recognition of useful astronomical work carried out under the auspices of the Association. The first award has been made to the Rev. T. E. R. Phillips, a past president of the Association and the director of its Jupiter Section. Mr. Phillips has for a long time been a most active planetary observer and draughtsman; he has brought out several memoirs on Jupiter, in which he has laid special stress on the rotation periods of different markings on the planet, and has detected several instances of abnormal motion. He wrote most of the descriptive articles on the planets in the new edition of the "Encyclopædia Britannica".

MR. PHILLIPS was president of the Royal Astronomical Society 1927–29, and was awarded its Jackson-Gwilt medal a few years earlier. He has also given much time to the observation of variable stars and double stars. He applied harmonic analysis to the variable star observations, and his results suggested their division into two groups which were differentiated by the relations between the first and second harmonics. Mr. Phillips's observatory is at Headley, near Epsom, Surrey. His two chief instruments are an 18-inch reflector bequeathed by the late Mr. N. E. Green to the British Astronomical Association, and an 8-inch refractor lent by the Royal Astronomical Society; the reflector has been remounted in an open lattice-work tube, which is found to give improved definition. The medal and gift will be presented by the president of the Association, Capt. Ainslie, at the annual general meeting on Oct. 29.

EARLY this month an expedition from the University of Cambridge will sail for Mombasa to carry out biological investigations of certain little-known lakes in Kenya and Uganda. The particular objectives will be Lakes Rudolf and Baringo in Northern Kenya and Lake Edward in Uganda. This follows upon interest in the ecological aspects of the great African lakes which was started by the Government fishing surveys of Lakes Victoria and Albert in 1927–28, and Miss P. M. Jenkin's recent work on the smaller lakes in the Kenya rift valley. The collections resulting will be deposited in the British Museum (Natural History), and since the lakes to be visited have never been examined thoroughly, it is anticipated that a number of new forms of life will be revealed. Work will be done on the chemistry and physiography of the lakes, and the ecology will be studied in as much detail as possible. Another side of the work will be the examination of high-level beaches around the rift valley lakes. This is expected to provide evidence concerning the previous land and water distribution during the African pluvial periods, additional to that already found by Mr. L. S. B. Leakey in Kenya and Mr. E. J. Wayland in Uganda. The expedition is being financed by the Royal Society, British Museum (Natural History), Royal Geographical Society, British Association, Percy Sladen Memorial Fund, Gloyne Fund, and the Cambridge Balfour Fund. It will be under the leadership of Dr. E. B. Worthington, and other members from Cambridge will be Mr. L. C. Beadle as zoologist and Mr. V. E. Fuchs as geologist and surveyor.

ON Sept. 25 the honorary freedom of the Borough of Kendal in Westmoreland was conferred on Sir Arthur Eddington, Plumian professor of astronomy and experimental philosophy in the University of Cambridge, in recognition of his high scientific attainments and contributions to knowledge. Sir Arthur was born on Dec. 28, 1882, in Kendal, where his father was headmaster of the Friends' School in Stramongate, a school in which John Dalton served for a time as assistant master. An appreciation which had been sent by Sir Oliver Lodge was read by Mr. H. C. Wilson, of Kendal, in presenting Sir Arthur to the Mayor. Sir Oliver referred to Eddington's mathematical work on the constitution of the stars and said that he is well known for his interpretation and extension of Einstein's work. Special tribute was paid to his gift of popular exposition. Sir J. J. Thomson, Master of Trinity College, Cambridge, also sent a tribute, in the course of which he said that "Sir Arthur is one of those rare cases where great literary is combined with great scientific ability". Sir Arthur, in replying, said that he was glad that "Kendal has recognised scientific work as service of public importance, not in any material sense . . . but perhaps in some fuller sense".

IN the course of its report, the Royal Commission on Agriculture in India dealt in detail with the possible scope and duties of the Imperial Agricultural Research Institute at Pusa, and recommended that a director possessing both administrative ability and experience in agricultural research should be obtained from Great Britain. The India Office has offered the appointment to Dr. B. A. Keen, of the Rothamsted Experimental Station, Harpenden, who will leave England on Oct. 7 on a year's leave of absence, which is being granted him by the Lawes Agricultural Trust with the concurrence of the Ministry of Agriculture. Dr. Keen joined the Rothamsted staff in 1913. At the outbreak of War he was commissioned to the Suffolk Regiment and served in Gallipoli and Palestine. On his return to Rothamsted in 1919, he became head of the Soil Physics Department, and in 1923 he was appointed to the new post of assistant director, which he still occupies. In 1924 he was elected a fellow of University College, London.

AT the Forestry Sub-Section of the British Association meeting at Bristol in September, Mr. Alexander

Howard, in a paper entitled "Our British-grown Hardwood Trees and Timbers", directed attention to the present heavy fellings and the almost total absence of replantings of the fine hardwood species of Britain —oak, ash, beech, elm, and so forth. Mr. Howard pointed out that the existing and often magnificent examples of these species in woods on private estates in Britain had resulted from the energetic and patriotic planting of the proprietors in the seventeenth and eighteenth centuries. Such plantings fell into abeyance during the nineteenth century, as the country and the nation's statesmen were no longer interested in hardwood timbers, owing to changed economic conditions. The latter-day imposition of heavy death duties has not only precluded the descendants of the former planters from carrying on the good work, but is resulting in the break-up of big estates, coupled with the felling, on an increasing scale, of large numbers of the magnificent trees and woods which have for so long made England famous as a beauty spot among the nations. Mr. Howard faces the fact that although the private proprietor may hope to make a profitable investment in planting coniferous woods, he can no longer hope to do so by planting hardwoods. The folly of the present system of taxation lies in the fact that timber represents so much capital which, on realisation, is being squandered by the recipients as soon as received.

REFERENCES are sometimes made in daily newspapers to the planting of trees by small-holders. Anyone conversant with this matter is aware that the mere planting of trees is but the first step: the results of such planting will depend on the technical supervision the trees receive during at least the first forty years of their lives; and the period in the case of hardwoods may well be longer. Mr. Howard points out that the Forestry Commission has limited its work mainly to softwoods and has as yet done little towards the replanting of hardwoods. His suggested remedy for the present position is to have a Government Forestry Department, which would have power to control all matters relating to forestry, to recommend expenditure, and to regulate all forests, without itself carrying on the trade of either planting, rearing, cultivating, felling, or selling. He considers that such a department might be in a very much better position. But under existing conditions in Great Britain, to which forestry practices in other countries have at present little application, a Government department, the sole work of which was to control all matters relating to forestry, recommend expenditure, and regulate all forests, would produce little of practical value. Mr. Howard states that: "Every man, woman, and child might be said to be a potential planter. All that is required is assistance and encouragement from the Government." If by this it is intended to imply that, given the money, the people will plant and look after trees, and that the results will be successful in the future, it is to be feared that Mr. Howard is unduly sanguine.

M. EM. TOUCHET, vice-president of the French Astronomical Society, makes a strong appeal in *La Nature* for Sept. 1 for the collaboration of amateur photographers in helping to get interesting and instructive photographs of lightning flashes and allied phenomena. The best methods of doing this were discussed by the French Society on Mar. 5 last and a résumé is given of the conclusions reached. Lightning is photographed in order to get a notable picture or for purely scientific purposes. In the latter case, the film should be changed after each flash. When a movable film is available, as when a cine camera is used, very instructive pictures can be obtained. Sometimes also the camera is rotated at a given rate about a vertical axis and excellent results obtained. Photographs are in existence showing successive flashes following exactly the same path. The size and kind of the camera used are not of great importance. M. Touchet says that a photograph taken with any kind of apparatus is better than no photograph at all. For example, it is most regrettable that although globular lightning has recently been seen hundreds of times, yet there is no authentic photograph of it in existence. With almost any portable cine camera an excellent photograph of it could be taken. Mathias has shown that at certain seasons and in certain mountainous regions these phenomena occur fairly often.

To obtain good stereoscopic photographs of lightning it is necessary to have two observers at stations about 200 metres apart. They can use electric torches for signalling to one another, or better, fix up telephone communication. Some good photographs have been taken in this way, the lightning standing out in relief. A table is given for the best length of base line to use for given focal lengths. Although with movable films it is possible to see roughly the true nature of the flash, we are still quite ignorant of its method of propagation. In general, the discharges are multiple; the first discharge blazes the way and the rest follow in the hot and ionised channel it has left. Traces of this channel are clearly shown by photographs. Between earth and cloud the discharges are nearly always multiple. In many cases the discharge is practically an 'electric arc' for an appreciable time and produces serious mechanical and calorific effects. Flashes between clouds, however, are generally simple. Lightning has often been observed curving towards the earth, and this has been attributed to the stratification of the atmospheric layers. There are many problems to be solved and the help of amateur photographers can be of the greatest assistance to meteorologists. The French Astronomical Society, Hôtel des Sociétés savantes, 28 rue Serpente, Paris, will gladly receive photographs of lightning, and those of scientific interest will be published in *La Nature*.

THE Bird Sanctuaries in the Royal Parks in and about London continue to do good work for the public as well as for the birds, and it is regrettable that a small minority of the people still abuses the privileges. The stealing of the eggs of Magellan geese in the Hyde Park and Kensington Gardens Sanctuary will be resented by none more than the public themselves. The Annual Report of the Sanctuaries Committee for 1929, now

again published in pamphlet form by H.M. Stationery Office (price 6*d.* net), gives many examples of improvements in the reserves. Undergrowth generally has been thinned to aid ground-feeding birds, clumps of brambles and nettles have been planted in Kensington Gardens, thickets in Greenwich Park, currant bushes, barberries, and teasels in Richmond Park, all to provide more food and cover to bird visitors. The lists of nesting birds and migrants show how great variety may be seen even in the heart of London. When the sun-bathers forsake the Serpentine, their places will be taken by immigrant ducks from the far north: there were 250 tufted ducks and more than 50 pochards last winter. Even a little auk from the open ocean visited the Round Pond. In these havens of peace, the struggle for existence goes merrily on: Magellan geese attacked all and sundry, herring gulls devoured the chicks of mallard, and mallard caught, drowned, and ate too venturesome sparrows. It is a lesson for those who would protect indiscriminately all the birds in a sanctuary or in a country.

IN a recent paragraph we referred to the work of the National Central Library (formerly the Central Library for Students), which endeavours to correlate in Britain the efforts of individual libraries to meet the needs of serious students. Readers may be reminded that this and several other British libraries take part in a much more extensive correlation scheme inaugurated by the International Institute of Intellectual Co-operation of the League of Nations. For several years this body has been endeavouring to collect information regarding the national and central libraries of different countries, with the view of creating a liaison between existing services. This was accomplished at the end of 1928, when a co-ordinating service of libraries was established by the International Institute. In order to increase the value of the co-ordination, at the request of an international congress of librarians held in 1929, there has just been issued a "Guide des services nationaux de renseignements du prêt et des échanges internationaux" (Paris: Institut International de Coopération Intellectuelle, 1930). In this appear concise notices of the centres of bibliographical information in every country where they exist or are in process of organisation, and in addition the addresses are given of all the bureaux for the international exchange of publications. Fifty-five nations or States are represented in the lists, an indication of the possibilities of this newly founded international service.

DURING the visit to Edinburgh of the French branch of the Franco Scottish Society on Sept. 26, the French Ambassador unveiled, at the Royal Edinburgh Hospital for Mental Diseases, a bust of Dr. Phillippe Pinel, the Paris physician who gained undying fame by his reformation of the old barbarous methods of treating the insane. Pinel was born on April 20, 1745, studied at Toulouse and Montpellier, and then went to Paris to study botany, zoology, and anatomy. He became known as a translator and editor of medical works, was made physician-in-chief at Bicêtre in 1792, and later held a similar position at the hospital of Salpêtrière. The reforms he introduced in both institutions led to the award of the Legion of Honour, and he was admitted a member of the Institute of France. He died on Nov. 25, 1826.

THE Council of the Television Society has recently taken steps to co-ordinate the experimental work of the members in such a manner that certain well-defined lines of collective research or group experimenting can be undertaken. A Research Committee has been formed to direct and assist members who desire to take an active interest in the work of the Society and in the advancement of the study of television. A survey is to be made of the membership, with special reference to technical qualifications and facilities of members to assist in experimental work; and educational institutions, universities, and commercial firms are to be approached to give facilities for group research. The Committee has undertaken to formulate definite group experiments, to be divided amongst members in such a way that their work, when completed, will form a definite contribution to our knowledge of the subject. These results will be edited and published in the Society's *Proceedings*, to be issued three times a year. As a preliminary step, the Committee has decided to consider a joint demonstration to be given at the annual exhibition of the Society to be held in April of next year.

THE Ministry of Agriculture desires that full use should be made by mycologists and plant pathologists in Great Britain of the facilities offered by the Imperial Bureau of Mycology. This Bureau has been supported financially by contributions from the governments of the Dominions, India, the Sudan, Iraq, and most of the Colonial Dependencies. The British government has hitherto not made any financial contribution, its aid having taken the form of the provision of a government building for use rent-free by the Bureau. A new and more commodious building has been erected to house the Bureau, near the Herbarium at Kew (at Ferry Lane, Kew), and arrangements are being made by which substantial financial aid shall be given in future by the three home governments, which will enable the Bureau to extend the scope of its activities. The Bureau is directed by Dr. E. J. Butler. For the purpose of dissemination of information, it publishes the *Review of Applied Mycology*, which gives a monthly survey of all current literature dealing with phytopathology and economic mycology from every part of the world. Imperial mycological conferences are held, under the auspices of the Bureau, at intervals of five years. It undertakes the identification and study of fungus and bacterial plant pathogens; and it maintains a museum of tropical plant diseases and a lending library for the use of mycologists.

As the result of a conference between the railway companies of France and the Minister of Public Works, a uniform system of electric signalling has been adopted and will be used on all the railways in France. The installation of the new electric visual system to replace the many mechanical systems in use will begin next year and will cost about £500,000. There are

important innovations made in the colour of the lights. The 'line free' signal, which is indicated at present by a white light, will in the future be signalled by a green light, thus bringing it into line with the colour used in all other countries. An orange-yellow colour indicates that the driver is to go slow. Violet will be used in shunting operations and to signify direction. The 'slacken speed' signal is given by two yellow lights placed horizontally followed by two yellow lights placed vertically. Red remains as the danger signal. The present use of mechanised systems which vary in different regions of France causes difficulty when engine-drivers are called upon to run trains over systems to which they are not accustomed. Trouble due to this cause was acute during the War. As the new signalling apparatus has been already tested on the Est, the État, and the Orleans lines, no difficulty is anticipated. An identical electrical system of luminous signals will be used in the day-time and at night.

AN instructive official table in connexion with international statistics of electric supply is published in the *Electrotechnische Zeitschrift* for June 12. It is compiled from the data collected by the international conference of high tension supply networks. The data show notable contrasts. In Switzerland, practically the whole population has electric supply available, whilst in Japan there is only about 20 per cent of the population similarly situated. England consumes 4·4 tons of coal per year per head of the population, which is the largest for any of the countries given. In Switzerland nearly 70 per cent of the available power is harnessed, whereas in Norway there is only about 15 per cent. The total maximum load per head of the population is credited to Norway, and Canada and Switzerland come next. The total capital cost of the generating and distributing systems in England is 222 million pounds, whilst in Canada it amounts to 157·5 million pounds. In the latter country, only about a third of the total is invested in distributing plant. The reason for this is that a very large fraction of the total energy is taken by large industrial consumers situated near to the generating stations. It is hoped that next year fuller international electrical statistics will be given. This is the first year of their publication and not many countries have sent in data.

THE principal international passenger traffic to and from Spain and Portugal, mainly for the capitals Madrid and Lisbon, passes through the frontier town of Irun near San Sebastian, where luggage is examined by the customs officers. From this town the main line follows the coast to San Sebastian and then turns off from the sea and gradually rises through the foothills of the Pyrenees to an altitude of 2000 feet, where the first ridge of the mountain is pierced by a tunnel which emerges at Alsasua. The section from Irun to Alsasua has been electrified by the North Spanish Railway; the Pajares mountain section and the suburban railways of Barcelona have also been electrified with direct current at 1500 volts. In the *Brown Boveri Review* for August there is an account of the express locomotives that have been built for the Irun-Alsasua section of the railway. Each locomotive is capable of developing 2700 h.p. at the tread of the wheels and is capable of hauling a passenger train weighing 400 tons (exclusive of the locomotive) at a speed of 40 miles an hour up an incline of 1·65 per cent. Special vacuum brakes are used and the braking force for the whole locomotive equals 177,000 lb. weight. There are six driving axles driven by six series wound motors which can be connected in various ways for altering the speed. Pantograph collectors with double bows are used to collect the current. Regenerative braking is also employed so that when going down hill electric power is generated by gravity. All the mechanical part of the locomotives was built by the Spanish Babcock and Wilcox Co. to the design of Swiss engineers.

MR. E. SHINWELL, M.P., the Secretary for Mines, has appointed Prof. Henry Louis to hold a local inquiry into the possibility of developing the production of gold and other minerals in Merionethshire.

DR. H. H. MANN, assistant director of the Woburn sub-station of the Rothamsted Experimental Station, is shortly leaving England for south Russia, to advise as to the possibility of the extension of the tea-growing industry. Before joining the Rothamsted staff, Dr. Mann was engaged in tea research in India, where he became recognised as one of the leading experts in the cultivation and management of the tea plant. He is expected to be away until December.

IN an article in NATURE of Sept. 20, p. 456, referring to the production of artificial pearls by Linnæus, the question was asked whether his experimental shells are still in existence. A correspondent has pointed out that the shells and also specimens of artificial pearls made by Linnæus are included in the Linnean Collection of Shells in the possession of the Linnean Society of London, and were among the exhibits from the Linnean Collections arranged in connexion with the Fifth International Botanical Congress held in August last.

PART 1. (Medical Tables) of "The Registrar-General's Statistical Review", 1929, has been issued (London: H.M. Stationery Office, price 7*s*. 6*d*.). The birth-rate for 1929, 16·3 per 1000 persons living, was the lowest that has been recorded. The death-rate was 13·4 per 1000, against 11·7 for the previous year, the rise being accounted for by the high mortality occasioned by epidemic influenza and the severe weather in February and March. The same cause increased the infant mortality to a rate of 74 per 1000 live births, or 9 per 1000 above that for 1928. The death-rate from cancer was 1437 per million living, against 1425 for the previous year, being the highest crude rate recorded. The rate for suicide was 126 per million, the highest figure on record. Deaths from accidental injury by mechanical vehicles on roads increased from 4492 in 1927 to 5251 in 1928 and 5799 in 1929, of which 1162 were caused by motor cycles.

THE new catalogue of the Wild-Barfield Electric Furnaces Ltd., Holloway, N.7, describes electromagnetic steel-hardening furnaces which have an

efficiency of about 90 per cent. This high efficiency is obtained by means of a special form of fan incorporated in the oven. At 100° C. this fan increases the rate of heating thirteen times and at 250° C. four and a half times. This effects great saving in the running costs. In the old days, steel was tempered by reheating the hardened steel until it assumed a certain colour due to the gradual formation of a film of oxide on it; the thicker the film the deeper the tint. Modern methods of tempering consist in reheating the steel either in a bath of oil, lead or salt, or in an air tempering oven. The last method is the cleanest and safest in operation. There are no fumes and the running costs are lower owing to the absence of salt or oil replacements. The introduction of forced circulation by a paddle fan makes it not only possible to heat the charge very rapidly but also to secure almost uniform heating. It is claimed that these furnaces can operate within 1° C. to any required temperature without attention.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:- An assistant in the Mechanical Engineering Department and two graduate assistants in the Mathematics Department of the Municipal Technical College, Coventry—The Director of Education, Education Department, Council House, Coventry (Oct. 6). An assistant analyst in the Health Department of the Municipality of Singapore—Peirce and Williams, 1 Victoria Street, S.W.1 (Oct. 6). A full-time lecturer in mining in the County Technical Institute, Worksop—The Principal, County Technical Institute, Worksop (Oct. 8). An assistant Government analyst, Hong Kong—The Private Secretary (Appointments), Colonial Office, 2 Richmond Terrace, Whitehall, S.W.1 (Oct. 8). A lecturer in experimental psychology in Otago University, Dunedin, New Zealand—The High Commissioner for New Zealand, 415 Strand, W.C.2 (Oct. 10). A clinical assistant at the Radium Institute—The Secretary, Radium Institute, Riding House Street, W.1 (Oct. 10). An assistant radiologist at the Middlesex Hospital—The Secretary-Supt., Middlesex Hospital, W.1 (Oct. 11). A bacteriologist and a senior bacteriological assistant under the Devon County Council—The County Medical Officer, 4 Barnfield Crescent, Exeter (Oct. 11). Two temporary drainage inspectors under the Ministry of Agriculture and Fisheries for technical work in connexion with land drainage—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (Oct. 13). A senior technical officer in the Admiralty Technical Pool—The Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1 (Oct. 15). A radiologist to the Royal Infirmary, Edinburgh—The Chairman, Royal Infirmary, Edinburgh (Oct. 20). A lecturer in the Department of Botany, King's College, London (special subject, plant physiology)—The Secretary, King's College, Strand, W.C.2 (Nov. 1). A Pilkington fellow in cancer research in the University of Manchester—The Registrar, University, Manchester (Nov. 15). A graduate for physics and mathematics in the County Technical and Secondary School, Workington—The Principal, County Technical and Secondary School, Workington.

Our Astronomical Column.

New Map of Mars.—*L'Astronomie* for September contains a new map of Mars, drawn by E. M. Antoniadi from his own studies of the planet, chiefly those made with the 33-inch refractor at Meudon. The map is a pictorial one, representing the telescopic aspect of each region, the gradations of light and shade being carefully reproduced. The map is in five portions: three of these have the equator in the centre, and extend to latitude 70° north and south, the projection being that of Mercator; each map covers 120° of longitude, the centres of the maps being at longitudes 310°, 70°, and 190°; the other two portions are circular, extending from latitudes 60° north and south to the poles. A large number of names are inserted, including those of many of the 'canals'.

M. Antoniadi rejects the view that the canals are arranged geometrically; he shows many of them as broad irregular stripes, others (notably Laestrygon and Antæus) as chains of lakes. Dotted lines indicate regions which have been observed to change either in shape or in tone during the period of his observations; these include five regions designated Nix (snow), but the so-called 'Dawes Ice Island' is not among them. The Solis Lacus is shown large and elongated, with some darker patches in it; five broad canals connect it with the surrounding dusky regions.

This is probably the most elaborate and detailed map of Mars that has been produced. There will doubtless be differences of opinion among observers as to some of the details, but few will dispute the artistic merit of the delineation. A new season of Martian observation will shortly commence, as the planet is in opposition next January in high north declination. This map may encourage new observers.

Galactic Rotation and the Spiral Nebulæ. The researches of the Mt. Wilson observers and those of Prof. de Sitter have established a strong case for the conclusion that the large recessional velocities of the spiral nebulæ are approximately proportional to their distances. Dr. J. H. Oort, who was one of the foremost workers on the problem of galactic rotation, contributes a paper to *Bull.* No. 196 of the Astronomical Institute of the Netherlands, in which he obtains a solution for the solar motion relatively to the nebulæ, which he compares with the solar motion derived from his solution of galactic rotation; the two prove to be in close accord, which tends to confirm his elements for the rotation, and also to give some additional weight to the assumption regarding the recessional motion of the spirals.

There is evidence of the existence of several clusters of spirals; such cases have been used not individually but in combination, the mean of such a group being given a higher weight than a single nebula. Dr. Oort is in doubt whether to treat the Magellanic Clouds as extra-galactic objects or not. Including them, he finds 360 km./sec. for the solar motion relatively to the nebulæ, directed towards galactic longitude 57°, N. latitude 2° (longitudes reckoned from the ascending node of the galaxy on the equator of 1900). Excluding the Clouds, he finds 380 km./sec. towards longitude 58°, N. latitude 4°. The recession of the nebulæ is found to be 140 km./sec. at Prof. de Sitter's unit of distance, which is 1,060,000 light-years; de Sitter and Hubble found 153 km./sec. and 151 km./sec. at this distance respectively. The previously adopted motion of the sun due to galactic rotation was directed towards longitude 57°, latitude 0°.

Research Items.

Chinese Alchemy.—The September number of the *Scientific Monthly* contains an interesting paper by Dr. Tenney L. Davis and Mr. Lu-Ch'iang Wu, of the Massachusetts Institute of Technology, on the development of alchemy in China. This contains some quotations from a paper by Ch'i-Ch'ao Liang which appeared in Chinese in 1923, dealing with the five elements, yin and yang, etc. The change in the meanings attached to these conceptions which arose under Taoist influences is (as in previous writers) supposed to have been the beginning of alchemy in China, which occurred, according to the explicit statements of the very reliable Ssu-ma Ch'ien (first century B.C.), during the reigns of Huang Ti (259-210 B.C.) and Wu Ti (156-87 B.C.). The earliest purely alchemical treatise in Chinese is considered to be that by Wei Po-Yang, who flourished about A.D. 142, extracts from which are quoted from a text recently printed. "In many respects it bears a strong resemblance to the later alchemical writings of the Europeans." Mr. Lu-Ch'iang Wu promises an English translation of Wei Po-Yang's work, and it is to be hoped that this will appear in due course.

Corn Customs in Wales.—The distribution of corn customs in Wales is the subject of a study by Mr. Iorwerth C. Peate in *Man* for September. Many people still living can remember customs relating to reaping the last sheaf of the corn in harvest. Six, eight, or more reapers standing in a circle hurled their sickles at the last tufts of corn, which had previously been divided into three and plaited by the chief reaper. If it were not cut down by one of the sickles thrown at it, it was cut by the head reaper. It was then taken to the farm and hung on a beam, where it remained until the next harvest, when it was destroyed. It was necessary that it should reach the beam dry, a matter of difficulty, as the farm women threw water, beer, milk, or other liquid at the carrier, who kept the sheaf concealed. The carrier's companions endeavoured to protect him by each pretending themselves to be the carrier. If successful, the carrier took the place of honour at the harvest feast; if unsuccessful, he paid a fine to the women, or was the butt of the harvest supper. Alternatively, the carrier might take the sheaf to the field of a neighbour where the harvest was still in progress, and throw the sheaf down before the principal reaper's sickle, immediately running away. The reapers threw their sickles at him and pursued him. If he were caught, he was bound with straw ropes and left in the field or thrown into a stream or drenched with pig-wash. These customs were not found in the central moorland area of Wales but coincide in distribution with the chief wheat-growing areas of the country. In most districts the custom died out in the latter half of the nineteenth century, owing to the religious teaching which followed on the revival of the eighteenth century, receiving its last blow in the great revival of 1859.

Some Bird Changes in Canada.—In the extreme south-west corner of Saskatchewan, Lawrence E. Potter has been observing birds for close on thirty years, and has found in that relatively short space considerable change in the avifauna (*Canadian Field Naturalist*, Sept., p. 147). Of few birds can it be said that there is an increase in numbers. The house-sparrow first appeared in 1907; the shelter and waste grain due to the settlement of the country induce the western meadowlark and the red-winged blackbird occasionally to stay over the winter; and the mourning dove has increased during the past ten years. Sometimes the numbers rise and fall without any apparent reason: magpies were fairly common in 1901–4; for six years thereafter they vanished altogether, and since their reappearance in 1910 they have multiplied so as to become a pest. On the other hand, the coming of the black-billed cuckoo in 1912 and its disappearance in 1924 coincided with the coming and going of unusual numbers of the tent caterpillar. In general, conditions of settlement have been found to be unfavourable to wild duck, birds of prey, sharp-tailed and sage grouse, and wading birds; and unaccountably the barn swallow has become very scarce. An interesting link is revealed in the connexion between bitterns and beavers. From about 1908 to 1918 beavers became very common and the American bittern flourished, for it found the shallow water caused by the beaver dams good feeding-places. But the beavers were wiped out about the latter date and they have never regained their former numbers; and the bittern has correspondingly decreased and is now rather rare.

Aphis Harvest of the Red Wood Ant. A few simple observations made by Fridthjof Ökland upon the use made by the red wood ant (*Formica rufa*) of the excreted juices of aphids, show clearly the importance of the relationship to this species of ant (*Biol. Zentralbl.* Bd. 50, p. 450, 1930). The author captured 200 ants on each of three species of trees, birch, pine, and fir, 100 as they marched up the tree trunk, and 100 as they marched down. The former were hungry ants on the way to their aphid pastures, the latter were fed ants returning. The difference in weight between the two groups represented the amount of aphis juices imbibed by 100 ants at one visit the dry weight of this difference averaged about 100 mgm. Observation showed that an ant paid about five visits a day, so that the amount of 'aphis-sugar' collected by an ant per diem would be 5 mgm., or during the summer months 500 mgm. Now the number of the inhabitants in a nest of the red wood ant have been reckoned at 150,000-200,000 individuals; suppose, on the safe side, we take the number to be 100,000, and that of these one-fifth are 'milk-gatherers'. Then the quantity of 'aphis-sugar' collected by a colony would amount to 10 kgm. a season, and the daily amount from one tree would be about 60 gm.—by no means an insignificant loss to the tree. Moreover, comparison with hive bees indicates that the aphis-sugar crop of an ant colony of several nests would be not less than the honey crop of a colony of hive bees.

Polar Limits of Tree Growth.—The Polish plant geographer, Dezydery Szymkiewicz, in his travels in high northern latitudes, has paid particular attention to this point, to which he devotes a paper in the *Acta Societatis Botanicorum Poloniae*, vol. 7, No. 1, 1930. His general conclusion is that trees are no more susceptible to low temperatures than other plants and that, as a result, there is no thermal limit to the northward spread of the tree habit. On the other hand, the desiccating effect of the cold dry winds prevalent in northern latitudes increases with the elevation of the foliage of the plant above ground level, and it is those arctic winds which are responsible for the absence of trees in the regions of frequent frost. The polar limit of tree growth, he therefore concludes, is really a maritime limit, and if the land masses were differently arranged, trees would be found nearer the poles.

The Movement of Continents.—The forces which, according to Wegener's theory, move the continents have been taken to be those due to the combination of the gravitational and centrifugal forces on the

continents and on the denser viscous magma on which they float. These give a resultant directed towards the nearer pole for a continent the centre of gravity of which lies above that of the displaced magma, and towards the equator if it is below. Dr. U. P. Lely, of The Hague, describes, in the issue of the *Physikalische Zeitschrift* for Aug. 1, experiments on the behaviour of a small piece of wood placed on the surface of water in a cylinder rotating about its axis, which was vertical. His results have led him to conclude that in the case of an elongated continent there is also a couple which may tend to set the long axis either parallel or at right angles to the meridian. In the case of Europe-Asia the couple is zero, of South America and Africa it is small, but in the case of North America it is large, and the American continent is bending at the equator. Dr. Lely considers that an examination of the directions in which the axes of elongated sunspots set should lead to important conclusions as to the distribution of density in such spots.

Meteorites in the Philippines.—The Director of the Weather Bureau of the Philippines, the Rev. M. Selga, has collected together in *Publications of the Manila Observatory*, vol. 1, No. 9, 1930, all the available information regarding meteorites in the Philippines. Seventeen cases are discussed, including twelve falls, two actual findings, and three sets of spurious examples. The earliest fall dates from 1618 and the latest from 1928. It is shown that the Mexico meteorite, which has been recorded as falling in Mexico in 1859, fell near the town of that name in the province of Pampanga; specimens are preserved in Paris, London, and Chicago. The Calivo meteorite fell in 1916 and analyses are now presented for the first time. The meteorite is a brecciated siderolite with 19 per cent of nickel-iron. The stony material is said to be mainly enstatite, but is clearly variable. One analysis gives 27·92 per cent of magnesium oxide, whereas another shows only 1·20 per cent, alumina and lime being high in this sample. A detailed petrographic examination appears to be called for, to complete the investigation. Reference is also made to the tektites found by Beyer in the province of Rizal since 1926. These occur in neolithic deposits and their composition places them between the australites and billitonites; the name *rizolites* is proposed for them. Their composition, form, lack of crystallites, and distribution all favour a cosmic rather than a terrestrial origin.

Sound Test Gramophone Records.—An addition to the number of gramophone records of scientific interest mentioned in NATURE of Nov. 9, 1929, Vol. 124, p. 741, has been made by the Parlophone Company's recent issue of two further sound test records. Each of these gives under normal conditions any one of a series of eight pure tones, covering in intervals of an octave a range of seven octaves, the lowest tones being respectively 32 and 50 vibrations per second. The playing duration of each tone is 40 seconds.

Rotatory Dispersion.—The issue of the *Physikalische Zeitschrift* for July 15 contains a summary by Dr. G. Kortüm, of the Chemical Institute of the University of Würzburg, of present-day knowledge of the optical activity of substances, and of the empirical and half empirical theories which have been advanced to connect the observations with the chemical properties of the substances. The general character of the optical rotation on the two sides of an absorption band is in keeping with the classical theory of Drude, but the constants calculated from the observations of rotation are not identical with those given by refraction and absorption measurements. The newer theories seek to connect the rotation either with the relation between the oscillations of the electrons or with the asymmetrical arrangement of the atoms within the molecule. They have, in the different forms in which they have been presented, met with a qualified success, and the recent observations of optical rotation in the ultra-violet are likely to provide means of testing them more severely. A list of more than 130 references is given.

Spectra of the Rare Earths.—The July issue of the *Journal of Research* of the U.S. Bureau of Standards contains a partial analysis of the spectra of lutecium, by W. F. Meggers and F. B. Scribner. This element is the heaviest of the rare earths, the spectra of which have been little studied, and has atomic number 71. As with hafnium, which was also under investigation recently in the same laboratory, auxiliary information, such as that provided by the Zeeman effect, was practically absent, and the classification of lines had to be carried out by their different behaviour under arc and spark excitation, and by the numerical relations between their wave-numbers. The normal states of neutral, singly ionised, and doubly ionised lutecium atoms have been found to be represented by ^2D, ^1S, and ^2S spectral terms, respectively, and there is evidence for the completion of the inner shell of f-type electrons, which is only partially filled in lighter rare earths, from the absence of certain terms from the first spark spectrum (Lu II). The closely allied problem of the correlation of the spectroscopic and magnetic properties of the rare earths has also been discussed recently by Prof. A. Sommerfeld in a paper in the *Sitzungsberichte* of the Vienna Academy of Sciences (vol. 139, p. 11).

Determination of Blood Cholesterol.—The determination of the blood cholesterol in clinical investigations is assuming growing importance and a simplified method has been described by Emily M. Day and A. Bolliger (*Australian Jour. Exper. Biol. and Med. Sci.*, vol. 7, pts. 1 and 2, 1930, p. 41). One cubic centimetre of blood or plasma is spread on two filter papers, No. 40 Whatman, 7 cm. diameter, and is dried in the air or in an incubator or paraffin oven. When dry, the filter paper is folded and placed in a dry, clean test tube 6 in. × ⅝ in.; chloroform (B.P. suffices) is added, sufficient to keep the filter paper well covered. The test tube (or tubes if several determinations are being made) is then put in a beaker or tin containing carbon tetrachloride up to about the same level as chloroform in the test tubes. This carbon tetrachloride bath is put into a water bath which is heated until the chloroform boils gently. Should the carbon tetrachloride start to boil, the heating is reduced; in this way the boiling of the chloroform is perfectly controlled. The chloroform is allowed to boil for 15 minutes; should it evaporate to the paper level, more is added. The chloroform extract is then poured into a graduated or volumetric flask and is made up to a known volume, conveniently 15 c.c., with several chloroform washings of the filter paper in the test tube. The cholesterol is estimated in an aliquot part of the extract, preferably 5 c.c., by adding 2 c.c. acetic anhydride and 0·1 c.c. concentrated sulphuric acid, and comparing the colour developed with that of a standard, similarly treated, in a colorimeter. The standard solution consists of 1 c.c. of a stock solution containing 0·1 per cent cholesterol made up to 15 c.c. with chloroform. The mixtures are allowed to stand in the dark for 10 minutes before being placed in the colorimeter. Calculation: $x = \frac{\text{Standard}}{\text{Reading}} \times 100$ mgm. per cent cholesterol. Comparison with other methods shows that the errors are within ± 5 per cent, even if only 0·2 c.c. of blood is extracted.

New Building for Mining Department of the University of Leeds.

THE new mining building which was officially opened by Viscount Chelmsford on Sept. 30 marks the first stage in the reconstruction scheme rendered necessary by the growth of the University of Leeds. Its erection has been made possible by the generosity of the Yorkshire Coal Owners' Association, which contributed £25,000 to the general building fund of the University, and of the Miners' Welfare Committee, which gave £10,000.

The main building is of three stories, and while the accommodation it provides is considered adequate for the immediate future, there exists considerable scope for extension should the need arise. The front of the building consists of Portland stone, and has been built to conform with the general architectural plans for the new University building scheme. The roof of the building is flat and is intended for use in the testing of surveying instruments and for latitude and azimuth observations.

On the top floor is a large well-lighted drawing office, a spacious room meantime used as a museum, a students' common room and departmental library, a research laboratory, and a large lecture theatre. In the museum numerous mining exhibits, historical and modern, are to be found. The wide corridors in both the top and middle floors are also utilised for the convenient display of geological specimens from many parts of the Empire and other exhibits of considerable importance to the successful teaching of mining practice.

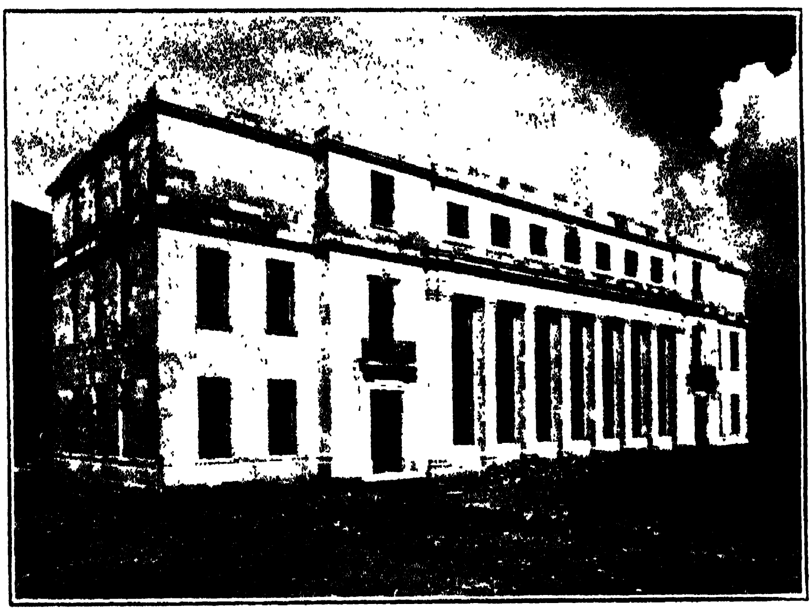

FIG. 1. Mining Department, University of Leeds.

The first or middle floor is apportioned into laboratories for wet and dry assaying, a gas-analysis laboratory, a dark room for photometric and safety-lamp work, a balance room, two research laboratories, and the departmental offices. The balance room is conveniently situated between the assaying and the research laboratories. One of the latter, and the research laboratory on the top floor, are to be occupied by a section of the Fuel Research Board for the physical and chemical survey of the West Yorkshire Coalfield. The other, and larger, research laboratory is fitted with all services necessary for the investigation of any physical or chemical problem associated with modern mining practice. It has so far been used by that branch of the Safety in Mines Research Board dealing with improvements in self-contained breathing appliances for use in mines. Entrance to any one of the laboratories on the first floor can be made only from the main corridor, a feature especially desirable in research work.

The ground floor comprises the main laboratory, crushing laboratory, sampling room, machinery room, ore bins, workshop, and stores. There are four independent means of access to this floor, two being at the front and two at the rear of the building. The main laboratory largely occupies the ground floor and is entirely given up to work on the preparation of coal and ores for the market. Working models of the principal appliances used in coal-cleaning and ore-dressing operations are installed. Adjacent to, but entirely separate from, the main laboratory is the crushing laboratory. Here an ore is treated, progressively if need be, by jaw crushers, rolls, stamps, and ball mills. The sampling room is completely isolated from the remainder of the building so as to reduce the risk of contamination during the grinding and subsequent treatment of coal or ore samples.

The principal units housed in the machinery room are: (1) a 25 h.p. vertical 2-stage air-compressor complete with all accessories required for testing purposes; (2) 32 h.p. motor-generator set with auto-transformer starter and six Reyrolles distribution panels; (3) full-size air-driven turbine chain coal-cutter kindly presented by Messrs. Anderson Boyes and Co.; and (4) two air-driven jigging-conveyor engines with lengths of troughs and accessories kindly presented by the British Jeffrey-Diamond Company.

In the basement, two 20-in. diameter Sirocco fans are installed together with about a hundred feet of fan gallery for experimental ventilation work. The fans are so arranged that they can be operated either singly, in series combination, or in parallel combination. A series of compressed-air pipe lines of various diameters is fitted along one of the walls of the basement, the arrangement incorporating different forms of metering devices, the whole being laid out for experimental work in compressed-air power service.

A special feature of the building is the ready accessibility of all services. In all there are twelve services, namely, a.c. two-phase, a.c. single-phase, d.c. power, electric lighting, water at mains pressure, water at constant head low pressure from the large capacity tank on the roof, domestic hot water, waste water, gas, compressed air, heating, and steam. Each service conduit system is painted a different colour, and the diagram giving the key to this colour scheme hangs in the main laboratory. In the laboratories the main services required are carried openly, along the top of, but are quite independent of, the benches. Tappings are arranged at intervals commensurate with the particular requirements. The cupboards below benches are all small standard-sized units and are readily removable or interchangeable. The general arrangement of the services is

thus one which facilitates their efficient maintenance and permits of ready extension whenever necessary.

All the electrical apparatus is earthed and adequately protected. Transformers for the supply of two-phase and single-phase a.c. are situated outside the main building, the distribution panels only being housed in the crushing laboratory. Reyrolle B.E.S.A. plugs (15 amp. and 5 amp.) are fitted throughout the laboratories for a.c. power and Reyrolle standard are used for d.c. The building is heated chiefly by the modern panel system, the panels being fitted on the walls or ceilings. Coke-fired boilers, separately housed in the basement, provide the hot water for heating and other purposes both in the Mining and the Fuel Departments.

Conference on Soil Science Problems.

THE Imperial Bureau of Soil Science, formed in May 1929 to assist workers on soil science throughout the Empire by providing technical information and promoting personal contacts between them, held its first Conference on Soil Science Problems on Sept. 16–18, at Rothamsted Experimental Station, Harpenden, with which it is in close association. The first day was made the occasion of the annual visit of Empire agricultural officers to the Station. The visitors, who included representatives from Australia, Canada, Ceylon, Gold Coast, India, New Zealand, Nigeria, Sierra Leone, South Africa, Straits Settlements, Federated Malay States, Sudan, Trinidad, Uganda, and Great Britain, were entertained to lunch, following a tour of the farm in which the classical and modern experiment plots were demonstrated. During the luncheon, the Conference was formally opened by the Right Hon. W. G. A. Ormsby-Gore; and later, an inspection of the laboratories was made and the work of the various departments demonstrated in groups, according to the individual interests of the specialist workers present.

The work of the Conference began on the following day, Sir A. D. Hall presiding, and a discussion on the mechanical analysis of soils was opened by Prof. G. W. Robinson (Bangor), who gave an account of the results of his work in comparing methods proposed by the International Society of Soil Science. He showed that similar figures were obtained by different methods with the majority of the soils examined. The main points of the discussion that followed were: The application of the proposed methods to tropical soils and the advisability of choosing a method suited to each particular class of soil; modifications in technique affecting the degree of dispersion of the soil by the omission, with some soils, of acid and peroxide treatment; and the proposed use of sodium hypobromite or chlorine peroxide for the oxidation of organic matter prior to analysis.

Mr. A. W. R. Joachim (Ceylon), who opened the discussion on available phosphorus and potash, spoke with particular reference to the reliability of laboratory tests for availability, such as the Dyer citric acid test and the physiological methods of Mitscherlich and Neubauer, suggesting that more use might be made of data for exchangeable potassium as an index of potash availability. During the discussion, reference was made to the desirability of eliminating errors due to seasonal effects and faulty sampling of the soil, and to the need of trustworthy, rapid, chemical methods to replace the tedious physiological tests. The suggestion was also made that the undoubted popularity of the latter methods on the Continent, and particularly in Germany, could be partly attributed, first, to a lower state of soil fertility than is prevalent in Great Britain; secondly, to unbalanced fertiliser additions, in the past, to soils in the same area, due in some cases to War shortage of one or other of the fertiliser components; thirdly, to legal difficulties involved in the sale of mixed fertilisers; and lastly, to conditions of land tenure.

A discussion on soil reaction and lime requirement was then opened by Mr. P. E. Turner (Trinidad) with an account of his work on the correlation of pH measurements of the soil with its degree of saturation with lime. This led to a discussion, principally on the correlation of pH values with other factors and the significance of soil reaction, especially in relation to the tolerance of specific plants.

At the afternoon meeting, the chairman, Dr. A. C. D. Rivett (Australia), opened a discussion on the work of the Imperial Bureau of Soil Science. Sir David Chadwick, secretary of the Executive Council of the Imperial Agricultural Bureaux, referring to the need of unity among research workers of the Empire which presaged the inauguration of the Bureau at the Imperial Agricultural Research Conference of 1927, said that the financing of the Bureau from a common fund derived from contributing governments marked a new departure in the constitution of the Empire. The work of the Soil Bureau for the year was then outlined by the Director, Sir John Russell. In the general discussion that followed, recommendations were made, many by overseas representatives, with the view of increasing further the usefulness and efficiency of the Bureau's activities. Finally, a proposal that the Bureau should hold annually a one-day informal conference was adopted.

The morning of Sept. 18, devoted to a discussion of soil survey, with Sir Thomas Middleton as chairman, began with an address on the soil resources of the Empire, by Sir John Russell, in which he said that no basis sufficiently broad to allow the comparative study of regions so widely scattered as those of the Empire has existed until recent years. The grouping of soils is determined, first, by climatic factors, and secondly, by geological factors. Topographical features also play an important part; but as first approximate generalisation, similar climatic conditions may be said to produce similar soil types and a tendency to form similar agricultural conditions. This is well seen in comparing the great regions of the British Empire and should serve as a basis for a valuable survey of the soil's resources. In concluding, he said that there is among manufacturers of the Empire a general working towards mutual agreements to reduce unnecessary competition and over-production; the agricultural scientific workers of the Empire are now organised through the Agricultural Bureaux to pool their information and ensure the maximum result for their efforts: it remains to bring about an organised agriculture for the Empire, based on sound soil and agricultural surveys, to ensure the best use of Imperial resources. A discussion on the position of soil survey in the Empire was then opened by Dr. F. J. Martin (Sierra Leone) with a description of a survey undertaken by him which resulted in an extension of rice-growing areas in Sierra Leone. Examples of similar extensions were brought forward during the general discussion. Sugar cane crops have been considerably extended in India through irrigation, by carrying out survey work which distinguishes between areas that would or would not respond to irrigation. The need for further work of that kind, especially in north-west India, and for

the examination and correlation of official data already available, was stressed.

Among other recommendations put forward in the next discussion, on the classification, mapping, and profile examination of soils, opened by Dr. W. G. Ogg (Edinburgh), were: That uniformity in the classification of soils could be furthered by discussions between surveyors of a large area at a central station; the more extended use of aerial photography in survey work; the use of single value factors and the data derived from examination of the clay fraction of the soil as aids in classifying soils; and the advisability of co-operation between soil surveyors and geologists.

The last discussion, on methods of field experimentation, presided over by Dr. P. J. du Toit (South Africa), began with an account by Dr. J. Wishart (Rothamsted) of plot layout in manurial experiments based on the statistical methods in use at Rothamsted. In further discussion he was able to put forward the advantages of the randomised block and Latin square methods over the older systematic arrangements. Errors in the analysis of yield data in fertiliser experiments on cacao or coconut trees due to lack of uniformity of seed or size of roots were instanced, and this led to a discussion on the most suitable size of plot to be adopted for tree crops, and to the further question of eliminating errors in pasture fertilisation experiments with grazing animals.

The first evening of the Conference was spent at a social gathering at Rothamsted, the second at a joint meeting of the British Empire Section of the International Society of Soil Science and the Soils Sub-Committee of the Agricultural Education Association. Prof. J. Hendrick (Aberdeen) deputised for Prof. N. M. Comber (Leeds) at this meeting, when the Russian Soils Congress and the organisation of the British Empire Section were dealt with in a partly informal discussion.

International Bibliography.

THE Institut International de Bibliographie was founded in 1895 by an international conference held in Brussels in response to the need to index the growing volume of recorded information. As the result of a thorough investigation of the problem, the logical principles of classification were developed, and it became possible to devise a classification, known as the Universal Decimal Classification, which is sufficiently extensive and flexible to index the literature of the world.

The Institute commenced to issue various bibliographies, of which the most important was a classified index to the literature of applied science with the title "Index technique". This publication is still being continued as the "Meddeelingen of the Nederlandsch Instituut voor Documentatie en Registratuur", and, though little known in Great Britain, is perhaps the most useful index of its kind.

The ninth annual conference of the Institute, held at Zurich on Aug. 21-25, was attended by delegates and members from all parts of the world. The British delegates were Sir Charles Sherrington, Sir Frederic Nathan, Dr. J. G. Priestley, and Dr. S. C. Bradford. In the absence of the president, Prof. A. F. C. Pollard, through illness, the chair was taken by M. W. Janički, the president of the newly formed Swiss section of the Institute. In a message to the conference, Prof. Pollard recommended that each national section of the Institute should prepare a list of the current periodical literature of its country, showing which literature has been indexed by the Decimal Classification and which awaits indexing, with the view of gradually building up complete classified national bibliographies.

A number of interesting papers were communicated. M. Paul Otlet recommended the establishment of a new scientific publication called "The Bibliographical Year", which should give an account of the advancement in bibliographical science. Sir Frederic Nathan read a paper in which he showed that the Association of Special Libraries and Information Bureaux arose spontaneously as the result of the pressing need for the supply of information to research workers, and gave an interesting account of the Association's activities; its Directory of Information Bureaux and Sources of Information, its Inquiry Bureau, the setting up of its Panel of Expert Translators, and culminating in its recent decision to recommend the general adoption of the Decimal Classification as a means of co-ordinating bibliographical undertakings.

M. B. Bourrel, director of the bibliographical information department of the Société des Transports en Commun de la Région Parisienne, gave an account of the application of the Decimal Classification to transport undertakings. In a succeeding communication M. Léon Walters, assistant director of the International Municipal Union, Brussels, considered the problem of classification from the point of view of municipal and local administration archives. Next, Dr. Walther, librarian to the Technical High School at Aix-la-Chapelle, dealt with the application of the Decimal Classification as a standard system from the point of view of scientific libraries, and traced the important developments in the use of the classification now taking place in Germany. The unequivocalness and completeness of the classification, as well as a possible simplification of the system by the deletion of certain auxiliary signs, was discussed by Dr. Hanauer, librarian to the Allgemeine Elektrizitätsgesellschaft.

Dr. Predeek, director of the library of the Technical High School, Charlottenburg, illustrated the usefulness of addressograph machines as means for printing catalogue titles and providing the subsequent reprints needed for a bibliographical service. M. W. Janički gave an interesting account of the historical development of bibliographical service in Switzerland. His compatriot, M. E. Mathys, librarian to the General Management of the Swiss Federal Railways, read a paper on the collection, cataloguing, and subject-matter indexing of professional literature, in which he discussed the establishment and running of information bureaux and inquiry offices, and showed the necessity both for national and international co-operation. Dr. Koch-Hesse, of Berlin, then illustrated the application of small-film photography to bibliographical purposes.

In a paper on the development of scientific bibliography in Great Britain, Dr. S. C. Bradford, Keeper of the Science Library at South Kensington, indicated the remarkable growth of institutions using the Universal Decimal Classification in Great Britain, from one to twenty-eight in four years. He showed that a complete bibliographical service comprises: (1) the survey of the literature being published, (2) its collection in the library, (3) the cataloguing and subject-indexing of the collected material, (4) the supply of bibliographies to research workers, (5) arrangements for the service of the books, either by reference, loan, or the issue of photo-copies—none of which departments had been organised satisfactorily up to the present. Dr. Bradford suggested that the material for a complete survey of the world's published literature would be provided if the principal library in each country should issue a weekly catalogue of all the publications of its country classified decimally. Such a catalogue would correspond to the list of accessions of the library, but would

need to be complete, up-to-date, and not necessarily to contain more than the publications of its own country. These weekly classified catalogues could then be used by the special librarian, both for book selection and as the actual author and subject catalogue-titles for his catalogues. The lists could also be amalgamated into a union catalogue of the world's literature. For the latter purposes, standard cataloguing-rules are needed as much as a standard classification. The divergencies in the cataloguing rules of different libraries were illustrated by the single example of the *Comptes rendus* of the French Academy, which was found to be catalogued under a different heading in each of the eight catalogues of large libraries consulted.

The Subject-Matter Index in the Science Library, to which are added all scientific references that are classified by the standard classification, has now grown in three years to more than one and a half million cards. This considerable repertory has been supplemented by gathering together as complete as possible a collection of miscellaneous scientific bibliographies, so that the Library is in a position to supply, so far as other work permits, really extensive bibliographies on scientific subjects in answer to inquiries.

As the result of the conference, the Commission of the Decimal Classification, which has control of the tables of the classification, has now been strengthened by including a delegate from each of the national sections of the Institute and from four of the principal State libraries, by the appointment of sub-commissions which will have charge of the improvement and extension of the different sections of the tables, and by the creation of a small executive committee with power to make small extensions that may be urgently required. Any modifications of the classification, which experience may show to be needed, will now be forthcoming without delay.

One of the most important decisions of the conference was that from next year the *Meddeelingen* of the Nederlandsch Instituut should be extended to include pure science and printed in a new form, bimonthly, under the title *Repertorium Technicum*. Each entry will bear the number which indicates its subject in the Decimal Classification, but, so that the bibliography may be useful to those who do not wish to employ the decimal classification, a small subject-index will be added to each part, and at the end of the year these indexes will be combined in an alphabetical index in three languages. An index of authors will be issued every year, or every two years. The bibliography will also be printed on loose leaves, so that, when it is not desirable to mount the titles on cards, the pages can be filed under the first decimal number on each page, in order to bring together entries on cognate subjects. In addition to references to articles, the *Repertorium* will be also a world-list of the more important technical books, so that it should be indispensable to librarians and research institutions of all kinds. The annual subscription will be £3.

In view of the simplicity and power of the methods of the Institut International de Bibliographie, it is astonishing that during the last thirty years or more so little use has been made of the bibliographical facilities provided by the Institute, the only explanation of which can be the almost complete lack of propaganda. Now that at last the methods of the Institute are beginning to be known, progress has already become rapid. As Sir Charles Sherrington remarked at the conference, scientific men are becoming aware of the need for guidance in the indexing of their publications, and the Institut International de Bibliographie is showing them the way.

S. C. BRADFORD.

University and Educational Intelligence.

BIRMINGHAM.—Under the will of the late treasurer of the University (Mr. Hugh Morton), the University will receive the sum of £20,000, to be applied at the discretion of the Council, in addition to £5000 for the foundation of two scholarships, one in English and the other in law. Of the ultimate residue of the estate, one half will accrue to the University, the other half being divided between the General Hospital and Queen's Hospital.

CAMBRIDGE.—The Vice-Chancellor announces that the late Miss R. M. Clark left to the University Observatory a legacy of £100.

Mr. H. W. Florey, of Gonville and Caius College, has been reappointed Huddersfield lecturer in special pathology.

ST. ANDREWS.—Payment has been received of a sum of £3000 bequeathed to the University by the late Dr. William J. Matheson, of Florida, U.S.A., for the institution of additional bursaries or scholarships in chemistry in the United College. It is proposed that a residential entrance scholarship in chemistry be instituted and that the existing Matheson Bursary should be made tenable for one year.

The new hall of residence for men students, St. Salvator's Hall, came into use on Oct. 2. Chattan House, hitherto occupied as a residence for men students, has been redecorated and furnished to receive women students who could not be accommodated in University Hall and its adjoining overflow houses. At the beginning of this session there will be about 220 students (including men and women) housed in residences under the management of the University.

THE next series of lectures and demonstrations on tropical hygiene, which are intended for men and women outside the medical profession proceeding to the tropics, will be given by Lieut.-Col. G. E. F. Stammers, on Oct. 8-10, 13-17, from 11 A.M. to 12.30 P.M. Syllabuses and full particulars can be obtained on application to the Secretary, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C.1.

PROSPECTUSES for the coming session have now been issued by technical colleges in London. The Imperial College of Science and Technology has a department of aeronautics which offers complete courses of lectures and laboratory work for graduate students and facilities and personal supervision for researches in every branch of the subject. The Battersea Polytechnic provides full day and evening courses in preparation for the University of London degrees in science and engineering and includes a Domestic Science Department and Training College, and a Department of Hygiene and Public Health. In six years its students are known to have obtained posts as follows: 189 as engineers, 167 as chemists or scientific assistants, 246 as health visitors or sanitary inspectors, etc., 504 as domestic science inspectors or teachers, 48 as art and handicraft teachers and designers. The Chelsea Polytechnic includes day schools and colleges of science and technology, pharmacy, metallurgy, housecraft, and chiropody, and evening classes in science, technology, and domestic subjects. The school of chiropody has a staff of 15 teachers and offers a two-year full-time course as well as a one year course (for older students) and a post-certificate one-year course. The Sir John Cass Technical Institute has departments of pure science, applied chemistry (including brewing and malting, gas manufacture, and petroleum technology), metallurgy, and navigation.

Historic Natural Events.

Oct. 5, 1091. Thunderstorm in England.—The "Anglo-Saxon Chronicle" records that "a marvellous sore tempest fell in sundry parts of England but especially in the town of Winchcombe, where (by force of the thunder and lightning) a part of the steeple of the church was thrown down, and the crucifix with the image of Mary standing under the rood-loft was likewise overthrown and shattered in pieces; then followed a foul, a noisome and a most horrible stink in the church". Five hundred houses were blown down in London, and Bow Church was unroofed. In Old Sarum the steeple and many houses were thrown down.

Oct. 5, 1570 (or 1571). Storms on English Coast.—There was a great storm of wind and rain in which many ships were lost and much damage was done on land. About midnight the Thames rose so high that it invaded the houses and a woman was drowned as well as many houses and cattle. The sea broke in between Wisbech and Walsoken and drowned a number of villages over a space of ten miles. At Yarmouth a great part of the bridge was carried away and the 'haven house' was carried six miles into the marshes and set down upright with the haven man and his wife. A ship was driven on a house, and some of the sailors climbed out on the roof. Bourne was overflowed to the midway of the height of the church, and boats were rowed over St. Neot's church walls. The water broke into the Wash and permanently flooded a great deal of low ground, destroying the dykes. The Stratford Avon ran so violently that it drove back the waters of the Severn, causing great floods and loss of cattle. A great part of the bridge by Magdalen College, Cambridge, was broken down and in all parts of the country many trees were uprooted.

Oct. 5, 1858. Donati's Comet.—On this date Donati's Comet was in conjunction with the bright star, Arcturus. The curved tail of the great comet, not unlike a gigantic quill pen, was then about 35° in length, and the head or nucleus was a brilliant object. The comet, discovered at Florence by Donati on June 2, was a striking naked-eye object seen from the northern hemisphere during September and October. It was last seen from the Cape of Good Hope Observatory on Mar. 4, 1859. The period is of the order of 2000 years.

Oct. 5, 1864. Storm Wave at Calcutta.—During a cyclone which swept over Calcutta the sea, rising ten feet above the highest spring tides, covered the whole of the level country at the mouth of the Ganges, causing a death roll of 45,000.

Oct. 5, 1881. The Tongking Typhoon.—The most frightful storm on the coast of Annam on record struck Tongking during the morning. The wind caused an abnormally high tide and heavy sea in the river; during the afternoon the waves broke through and washed away the banks, flooding the whole countryside. During the night the storm increased in intensity until there was 6 feet of water in houses three or four miles from the shore. Two thousand houses, 200 churches, and nearly 100 junks were destroyed; there was great loss of life and the whole district was ruined. The s.s. *Quinta* went ashore on the coast of Hainan and was a total loss.

Oct. 8, 1530. Floods in Italy.—Following three days of bad weather, with thunderstorms and heavy downpours of rain, a great flood of the Tiber invaded Rome, destroying 600 houses and causing the loss of 12,000 lives. At about the same time there was a great inundation of the sea in Venice.

Oct. 8, 1726. Aurora.—Descriptions of this notable aurora are given in *Phil. Trans.*, 1726. As seen from the south of England, the display began about 6 P.M., spread from the northern horizon to all parts of the sky, and, after culminating in activity about 8 P.M. (when a short-lived corona appeared near the zenith), died away after 2 A.M. on Oct. 9. The formation of the corona was preceded by pulsating streamers and cones of light which shot up towards the zenith, first, from an arch in the northern sky and, later, from all parts of the horizon. The display seems to have been similar and but little inferior to that of Mar. 6, 1716, which aroused great interest. It was surmised by one observer that the origin of the phenomenon was "a thin Cloud composed of a Sulphureous Exhalation, hanging over us in the Air, at a considerable Height" that took fire; further, that "they are, doubtless, of great use to the Peace and Safety of the Earth, by venting some of that pernicious Vapour and Ferment that is the Cause of those terrible Convulsions, which Earthquakes are accompanied with". According to Wolf, a sunspot maximum fell during 1727.

Oct. 8, 1871. Great Fire of Chicago.—In 1871 the greater part of Chicago was built of wood, which was very dry after an almost rainless summer. On Oct. 8 a fire broke out near the lumber district west of the city, and spread rapidly under the influence of a strong wind. Except for the San Francisco fire of 1906, this was the greatest fire of modern times; in 27 hours 17,450 buildings were destroyed and 100,000 people rendered homeless, while 250 lost their lives. The destruction would have been even more complete but for opportune rain on Oct. 10.

Oct. 10, 1780. Hurricane in Barbados.—Barbados was devastated by a hurricane which began on the morning of Oct. 10 and continued for 48 hours. In the afternoon of the first day all the ships were driven from their anchors to sea. In the night Bridgetown was laid nearly level with the earth, and by daylight not one building on the island was undamaged. Most of the livestock and 4326 persons perished, and the loss was estimated at more than a million sterling. It was officially reported that a 12-pound gun was carried by the wind and waves from the south to the north battery, a distance of 140 yards. Other islands in the Lesser Antilles suffered equally; in Martinique 9000 lives were lost and in St. Lucia 6000, and the British and French warships, of which there were many in those waters, were badly damaged. The course of this storm was afterwards worked out in detail by Reid from the logs of those ships.

Oct. 11, 1737. Destructive Indian Earthquake.—A violent earthquake and hurricane visited Calcutta and the surrounding district. It is said that the lofty steeple of the English Church sank into the ground without breaking. The water of the Ganges rose 40 feet above its usual level. About 20,000 ships were lost, while 300,000 persons, it is estimated, were killed.

Oct. 11, 1918. Earthquake in Porto Rico.—The epicentre of this earthquake lay in the north-eastern portion of Mona Passage, a deep submarine valley, the slopes of which are so steep that they appear to be fault-formed. A few minutes after the earthquake a sea-wave about 16 feet high swept over the north-west coast of the island. During the half-century before, this coast had been subsiding, and the earthquake and sea-waves may have been caused by a displacement along one side of the submarine valley.

Oct. 11–12, 1737. Cyclone in Bengal.—A great cyclone crossed the Bay of Bengal and entered the mouth of the Ganges, where a cyclonic wave rose 40 feet above the usual level of the river. It is stated that this wave drowned 300,000 men.

Societies and Academies.

London.

Institute of Metals (Annual Autumn Meeting at Southampton), Sept. 11.—**J. C. Hudson**: The effects of two years' atmospheric exposure on the breaking load of hard-drawn non-ferrous wires. The losses in strength after two years' exposure are very small; the majority of non-ferrous materials are very resistant to atmospheric corrosion. Brass is an exception, as its strength is adversely affected by the copper redeposition that accompanies atmospheric corrosion.—**W. H. J. Vernon** and **L. Whitby**: The open-air corrosion of copper. (2) The mineralogical relationships of corrosion products. Complete agreement with the formula of the corresponding mineral has been realised in products after seventy years' exposure and upwards. Basic copper sulphate (under most conditions the major constituent) then coincides in composition with brochantite, $CuSO_4 . 3Cu(OH)_2$; basic copper chloride (in products near the sea-board) with atacamite, $CuCl_2 . 3Cu(OH)_2$; basic copper carbonate (usually present but in minor proportion) with malachite, $CuCO_3 . Cu(OH)_2$. After shorter periods of exposure the basicity of the product is lower than that of the corresponding mineral.—**E. Voce**: Silicon-copper alloys and silicon-manganese copper alloys. A survey of these alloys, studying their mechanical and physical properties in the cast, drawn, and rolled conditions, with the view of developing and extending their uses.—**E. Vaders**: A new silicon-zinc-copper alloy. The range of the α-solid solution phase at the copper end of the diagram has been determined; the 90 per cent copper alloy can take up 4·5 per cent silicon into solid solution. Alloys with 2-5 per cent silicon and 70-90 per cent copper have valuable properties. The best alloys within this range are those with 80-82 per cent of copper; these can be forged hot, rolled, and extruded, and give good castings, which have a dense uniform structure free from shrinkage cavities even in the thickest parts.—**H. C. Dews**: The effect of phosphorus on the strength of Admiralty gun-metal. Phosphorus up to approximately 0·05 per cent has little effect on the mechanical properties or structure. Above 0·05 per cent phosphorus causes the appearance of free Cu_3P and at the same time a reduction in the mechanical properties.—**F. Hargreaves**: Heat-treatment, ball-hardness, and allotropy of lead. From quenching and ball-hardness tests on lead of high purity, it is suggested that lead is allotropic, the suggested critical points being 187° C. and 228° C., approximately. The hardness varies greatly with the heat-treatment. Very marked changes take place in the hardness immediately after quenching. The presence of 0·005 per cent tin inhibits these marked changes, and they do not take place in commercially pure lead.

Paris.

Academy of Sciences, Aug. 25.—**Georges Urbain**: Notice on Achille Le Bel.—**Louis Blaringhem**: An autofertile hybrid of *Ægilops ovata* and *Triticum dicoccum*.—**A. Yersin**: Some observations on atmospheric electricity in Indo-China.—**Cl. Chevalley**: A theorem of Hasse.—**Georges Durand**: The application of the ideas of convexity and of contingent to obtaining certain criteria of enumeration.—**Nikola Obrechkoff**: Series of functions.—**A. P. Rollet** and **L. Andrès**: The cæsium borates. Evidence has been obtained of the existence of three cæsium borates, possessing 5, 3, and 1 molecule of boric anhydride to 1 molecule of Cs_2O.—**L. Bert** and **P. Ch. Dorier**: A new method of synthesis of cinnamic alcohol and its homologues.—**R. Weil**: New observations on quartz.—**M. Blumenthal, P. Fallot**, and **A. Marin**: Geological observations on the limestone of the Spanish Rif of Djebel Musa at Xauen.—**Th. Biéler-Chatelan**: The quaternary polysynthetic glacier of Monti Simbruini (Central Apennines). The limits of its extension.—**H. Hérissey** and **J. Cheymol**: Vicioside. This substance has been isolated from the vetch by methods similar to those described by Ritthausen, but the presence of galactose, found by this author after hydrolysis, could not be confirmed: the only sugar produced was *d*-glucose.—**Louis Emberger**: A climatic formula applicable in botanical geography.

Sept. 1.—**L. Filippoff**: The astronomical determination of the period of the disappearance of Atlantis. Atlantis existed during the Quaternary period and disappeared about 7256 B.C.—**S. Carrus**: The determination, without the square sign, of various expressions relating to skew curves by means of two arbitrary functions capable of defining the radii of curvature and of torsion of the curve.—**Serge Tchounikhin**: Simplicity of the finite group and the orders of its classes of conjugated elements.—**L. S. da Rios**: The theory of vortices.—**H. Pélabon**: New copper oxide rectifiers. In a preceding communication the author has suggested the existence in the active layer of an unsymmetrical condenser consisting of a copper armature, a semiconductor (cupric oxide) separated by an insulating layer of cuprous oxide. To test this view, a condenser has been formed of a metal, a semiconductor of pure copper oxide moulded into pastilles, separated by a semi-insulating layer of gold powder in suspension in varnish, the whole being placed under pressure. This arrangement possessed unilateral conductivity and acted as a rectifier for alternating currents.—**E. Rinck**: The equilibrium in the fused state between calcium, sodium, and their chlorides.—**J. Barbaudy** and **A. Lalande**: Some properties of absolute alcohol.—**Albert Portevin** and **Pierre Chevenard**: The change of composition of the cementite constituent in the course of reheating special steels.—**A. Nowakowski**: The study of certain cellulose and glucose esters by means of the X-rays. The results obtained are in good agreement with the conclusions which may be drawn from the cellulose model suggested by Sponsler and Dore and by Meyer and Mark.—**Paul Remy-Genneté**: The action of hydrogen and of hydrocarbons on barium. Barium slowly combines with hydrogen at the ordinary temperature, but methane and acetylene after a month in contact show no trace of absorption, and it is suggested that this fact might form the basis of a method of analysis. Carbon monoxide does not react with barium.—**M. Prettre, P. Dumanois**, and **P. Laffitte**: The inflammation and combustion of mixtures of pentane and air. In a previous paper it has been shown that there are two visible stages of combustion of pentane in air, one at 270°-300° C. and the other at 660° C. The effect of antidetonant substances on the lower temperature phase of the combustion has now been studied. The antidetonants included benzene, tin tetrethyl, and lead tetrethyl: the effect of adding these substances to the pentane was to reduce and finally to suppress the luminosity of the low temperature stage of combustion.—**Ch. Courtot** and **V. Ouperoff**: Study of the action of aluminium chloride on the arylalkyl, alkyl, and hydro-aromatic ketones in the presence of tertiary aromatic amines.—**Louis Emberger**: The stage of vegetation.

Diary of Societies.

FRIDAY, OCTOBER 3.

SOCIETY OF CHEMICAL INDUSTRY (Manchester Section) (at "The Manchester" Limited, Royal Exchange, Manchester), at 7.—B. D. Porritt: Some Aspects of Standardisation.
JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—S. J. Crispin: The Development of the Bridge.
TEXTILE INSTITUTE (at Manchester), at 7.30.—J. Smeaton: Textile Specifications and their Preparation.

SATURDAY, OCTOBER 4.

ROYAL SANITARY INSTITUTE (in the Assembly Room, Town Hall, Hereford), at 10.—Councillor Mrs. Luard: The Place of Women in Local Government.—G. H. Jack: The Preservation of the Countryside.—Councillor J. R. Barker: The Health Authority and the Milk Supply.
BIOCHEMICAL SOCIETY (in Biochemical Laboratory, Cambridge), at 3.—E. L. Smith and V. Hazley: (a) Action of Antimony Trichloride with Cod-liver Oil and its Unsaponifiable Fraction; (b) A New Technique for the Antimony Trichloride Colour Test.—B. C. Guha: Observations on the Newer Factors Necessary for the Normal Growth of the Rat.—K. H. Coward, F. J. Dyer, K. M. Key, and B. J. E. Morgan: A Quantitative Method for the Biological Estimation of Vitamin A.—B. Woolf: The Addition Compound Theory of Enzyme Action.—Dr. M. Nierenstein, J. C. Pool, and N. V. Price: Pyrogallase, a New Enzyme.—T. Moore: The Distribution of Vitamin A and Carotene in the Body of the Rat.—B. H. E. Cadness and C. G. L. Wolf: Urinary Proteases.—A. N. Drury and L. J. Harris: Vitamin B Deficiency in the Rat, Bradycardia as a Distinctive Feature.—W. Ramsden: Denaturation of Proteins by Urea.—R. P. Cook, Prof. J. B. S. Haldane, and L. W. Mapson: The Action of Carbon Monoxide on the Oxidation of Certain Substances by *B. coli communis*.—M. Stephenson and L. H. Stickland: Bacterial Reductions of Molecular Hydrogen.—A. Patey and B. E. Holmes: Preliminary Observations of a Biochemical Nature on the Tumour-Producing Filtrates from the Rous Sarcoma.—D. R. P. Murray: The Inhibition of Esterases by Excess Substrate.—Demonstration by R. P. Cook, Prof. J. B. S. Haldane, and L. W. Mapson: The Use of the Barcroft Manometer in Determining the Respiration of Tissues in the Presence of Mixtures of CO and O_2.
INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch) (at the College of Technology, Manchester), at 4.—R. W. Stubbs: Presidential Address.
INSTITUTION OF MUNICIPAL AND COUNTY ENGINEERS (South-Eastern District) (at Beach House Park Pavilion, Worthing), at 4.45.—P. E. Harvey: Notes on Recent Works at Worthing.—B. V. Bradforth: The Storm-Water Problem at Worthing.

MONDAY, OCTOBER 6.

SOCIETY OF ENGINEERS (at Burlington House, Piccadilly), at 6.—Lieut.-Col. H. C. Hawkins: Some Impressions of America.
IRON AND STEEL INSTITUTE (Joint Meeting with the Cleveland Institute of Engineers) (at the Cleveland Technical Institution, Middlesbrough), at 7.30.—H. C. Wood: Open-hearth Furnace Steelworks: a Comparison of British and Continental Installations and Practice.—J. Šarek: What Reasons compelled the Prague Ironworks to Introduce Thin-walled Blast-furnaces.—A. Kříž: The Heterogeneity of an Ingot made by the Harmet Process.—L. W. Schuster: The Effect of Contamination by Nitrogen on the Structure of Electric Welds.—O. Quadrat: A Contribution on the Problem of the Analysis of Basic Slags and the Representation of their Composition in a Triangular Diagram.
HALIFAX TEXTILE SOCIETY (at Friends' Meeting House, Halifax), at 7.30.—B. S. Rowntree: Unemployment.
INSTITUTE OF METALS (Scottish Local Section) (at Institution of Engineers and Shipbuilders in Scotland, 39 Elmbank Crescent, Glasgow), at 7.30.—Aluminium Review and Visit of the President.
SOCIETY OF CHEMICAL INDUSTRY (London Section) (jointly with Chemical Engineering Group) (at Institution of Civil Engineers), at 8.—Dr. E. Hauser: Recent Results in Structural Research of Colloids in Science and Industry.

TUESDAY, OCTOBER 7.

INSTITUTION OF HEATING AND VENTILATING ENGINEERS (at 20 Hart Street, W.C.1), at 7.—G. L. Copping: Power Plant Chimney Pollution.
INSTITUTE OF METALS (Birmingham Local Section) (in Chamber of Commerce, Birmingham), at 7.—T. G. Bamford: Chairman's Address.
IRON AND STEEL INSTITUTE (Joint Meeting with the Lincolnshire Iron and Steel Institute) (at the Secondary Schools, Doncaster Road, Scunthorpe), at 7.—F. Bainbridge: Developments in Fuel Economy at Skinningrove.—J. A. Jones: Chromium-Copper Structural Steels.
IRON AND STEEL INSTITUTE (Joint Meeting with the Sheffield Metallurgical Association) (at 198 West Street, Sheffield), at 7.30.—D. F. Campbell: High-Frequency Steel Furnaces.—W. H. Hatfield: Permanence of Dimensions under Stress at Elevated Temperatures.—A. Kříž: The Heterogeneity of an Ingot made by the Harmet Process.—H. C. Wood: Open-hearth Furnace Steelworks: a Comparison of British and Continental Installations and Practice.
INSTITUTION OF AUTOMOBILE ENGINEERS (at Royal Society of Arts), at 8.—Sir Herbert Austin: The Future Trend of Automobile Design (Presidential Address).

WEDNESDAY, OCTOBER 8.

ILLUMINATING ENGINEERING SOCIETY (at 15 Savoy Street, W.C.2), at 6.30.—Report on Progress in Illuminating Engineering, and Display of Exhibits illustrating Recent Developments in Illumination.
TELEVISION SOCIETY (at University College), at 7.—J. H. O. Harries: Some Developments in Television based on Quantitative Analysis (Lecture).
INSTITUTION OF AUTOMOBILE ENGINEERS (Leeds Centre) (at Metropole Hotel, Leeds), at 7.15.—Sir Herbert Austin: The Future Trend of Automobile Design (Presidential Address).
INSTITUTION OF CHEMICAL ENGINEERS (at Chemical Society), at 8.—Dr. S. J. Kohli: The Effect of Surface Conditions on Heat Transmission.
EUGENICS SOCIETY (at Linnean Society), at 8.30.—Dr. E. B. Turner and others: Quinquennial Health Assessments—(a) Unemployables; (b) National Health Insurance.

THURSDAY, OCTOBER 9.

INTERNATIONAL SOCIETY OF LEATHER TRADES' CHEMISTS (British Section) (at Royal Agricultural Hall), at 10 A.M.—H. Bradley: Some Physical Properties of Leather.—R. H. Marriott: The Origin of Ammonia in Lime Liquors.—G. E. Knowles: Study of Dyes Suitable for Dyeing Synthetic Tanned Leather.—W. R. Atkin: Effect of Heat on Chrome Alum Solutions.—E. C. Line: Some Applications of the Microscope in Leather Manufacture.
ROYAL AERONAUTICAL SOCIETY (in the Lecture Hall of the Royal Society of Arts), at 6.30.—C. R. Fairey: The Growth of Aviation.
INSTITUTE OF METALS (London Local Section) (at Society of Motor Manufacturers and Traders, Ltd., 83 Pall Mall), at 7.30.—W. T. Griffiths: Chairman's Address.
INSTITUTION OF WELDING ENGINEERS (at the Engineers' Club, Albert Square, Manchester), at 7.45.—J. Ryder: The Training of Operators in the Welding and Cutting Industries.

FRIDAY, OCTOBER 10.

ROYAL SANITARY INSTITUTE (in the Guildhall, Nottingham), at 4.30.—Alderman A. R. Atkey: River Pollution.—Dr. L. P. Lockhart: Industrial Medicine in Relation to Public Health.
IRON AND STEEL INSTITUTE (Joint Meeting with the Local Branch of the South Wales Institute of Engineers) (at the Royal Metal Exchange, Swansea), at 7.—A. Kříž: The Heterogeneity of an Ingot made by the Harmet Process.—H. C. Wood: Open-hearth Furnace Steelworks: a Comparison of British and Continental Installations and Practice.—O. Quadrat: A Contribution on the Problem of the Analysis of Basic Slags and the Representation of their Composition in a Triangular Diagram.
JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—S. Dunlop: The Refining of Cane Sugar.
INSTITUTE OF METALS (Sheffield Local Section) (in Mappin Hall, Applied Science Department, University, Sheffield), at 7.30. Prof. F. C. Thompson: Some Observations on the Wire Drawing Process (Sorby Lecture).

SATURDAY, OCTOBER 11.

INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch, Burnley Section) (at the Technical College, Burnley). F. Griffiths: Belgian Moulding Sands in the Iron Foundry.

PUBLIC LECTURES.

SATURDAY, OCTOBER 4.

MATHEMATICAL ASSOCIATION (at Bedford College), at 3.—W. C. Fletcher: Napier's Method of Constructing Logarithms and its Advantages for School Use.

MONDAY, OCTOBER 6.

UNIVERSITY COLLEGE, LONDON, at 2.30.—Sir Flinders Petrie: Egyptian History before the 18th Dynasty.
ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Prof. W. H. Park: Pneumonia: The Types of Pneumococci in Adults and Children and their Significance (Harben Lecture 1).

TUESDAY, OCTOBER 7.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Prof. W. H. Park: Pneumonia: The Epidemiology; the Refining of Antipneumococcus Serum (Harben Lecture 2).
KING'S COLLEGE, LONDON, at 5.—Dr. J. W. Pickering: Blood Plasma and Platelets. (Succeeding Lectures on Oct. 14, 21, and 28.)

WEDNESDAY, OCTOBER 8.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Prof. W. H. Park: Pneumonia: The Therapeutic Use of Vaccines and Antibacterial Sera (Harben Lecture 3).

THURSDAY, OCTOBER 9.

BEDFORD COLLEGE, at 2.—Prof. Wilson: General Physics.—At 5.—Dr. P. Hopkins: A Psycho-Analytic Study of Jeremy Bentham as a Type of Social Reformer.
ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Rev. Dr. A. H. Gray: Christian Civilisation and Contraception.
UNIVERSITY COLLEGE, LONDON, at 5.30.—R. Engelbach: Recent Discoveries in Egypt.—Prof. H. Spemann: Introduction to the Theory and Practice of Experimental Embryology (in English). (Succeeding Lecture on Oct. 10.)

SATURDAY, OCTOBER 11.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. W. G. Ivens: Native Life in the Solomon Islands.

CONGRESS.

OCTOBER 15 TO 23.

INTERNATIONAL CONGRESS OF HYDROLOGY, CLIMATOLOGY, AND MEDICAL GEOLOGY (at Lisbon).

SATURDAY, OCTOBER 11, 1930.

CONTENTS.

Editorial and Publishing Offices:

An English Folk Museum.

THE discussion on folk museums which took place in the Anthropological Section of the British Association at the recent Bristol meeting was singularly opportune. Following within a week or two on Mr. Lansbury's announcement of the appointment of a committee representing the Office of Works and the Board of Education to consider the question of the institution of such a museum in London, it furnished the occasion for educating public opinion on the nature and scope of the folk museum as it presents itself to those who have this matter at heart; at the same time it set out the grounds upon which the plea of urgency is held to justify such a proposal at a time when the financial conditions in Great Britain are anything but favourable to an undertaking of this kind.

The communication from Sir Henry Miers with which the discussion opened, and from which we print extracts elsewhere in this issue, was an admirably lucid and comprehensive survey of the situation in regard to folk museums both in England and on the Continent. After defining what he understood by a folk museum and briefly describing the various types of collection which may be brought within the definition, he pointed out that the proposal to set up a folk museum for England is by no means new. On many occasions during the last twenty years or more, the formation of a national folk museum has been urged with some insistency. Nothing has been done. A number of museums now include collections of folk material of varying size and importance for scientific study; but there is nothing which can be regarded as in the nature of a national collection.

With the issue of the Report of the Commission on National Museums and Galleries, the situation has changed. It is the definite recommendation of the Report that a folk museum for England should be established, and it even goes so far as to suggest two possible sites—the Botanic Society's grounds in Regent's Park, soon to be vacated, and Chiswick House. The recommendation has brought to a focus the efforts of those who for so long have seen the desirability—perhaps it would not be too much to say the necessity—of action in this direction before it is too late. In consequence, the Folk Museum Committee of the Royal Anthropological Institute, strengthened by the co-operation of the Royal Society, the British Association, the Folk-Lore Society, the Royal Society of Arts, and the Museums Association, has carried matters to a point at which a specific proposal is under official consideration.

Now that the question has reached this stage, there are certain considerations which should be kept to the fore. First and foremost, there is the matter of urgency. This emerges clearly when the nature and scope of the proposed museum are taken into account. It is suggested that in the main it should be of the open-air type, such as that at Skansen, the prototype of all existing open-air museums. The museum will confine itself to the arts and crafts, the surroundings and accompaniments of the daily life in past ages of the peasant and artisan—what is generally, if inaccurately, called the working class population. It is considered, and quite rightly, that the life and culture of the middle and upper classes is adequately illustrated already in other institutions. An essential feature of the proposed museum, however, is that this material should be exhibited in its natural surroundings—the appropriate setting of the actual houses, the humbler buildings and cottages, of the different periods of English domestic architecture in which it was used, each article of furniture in its appropriate room, each implement, each utensil, in its proper place, as if ready to hand.

Barns and other outbuildings of the farm, the smith's forge, wind- and water-mill, and other material accompaniments of the social and economic life of the English village, must be included to fill in the picture. The maypole on the village green, and possibly the holy well, will illustrate other sides of country life, even perhaps on occasion to be supplemented by the performance of folk- and country dances. On the other hand, for purposes of instruction, as well as of display and safety, a number of objects will have to be exhibited in an annexe in conditions more nearly approaching those of the ordinary museum. In this additional building also might be housed such administrative offices as are required.

It is scarcely necessary to enlarge upon the nature of the objects which should and could be brought together in such a collection, or to dwell upon their value from a scientific and educational point of view in illustrating the culture and character of the English people in the past. It should be realised, however, and that very clearly, that the opportunity for forming such a collection is growing less and less almost day by day. Those who know the rural districts of England will have seen here and there obsolete implements and domestic appliances, sometimes carefully cherished by those who have known their use in their youth, sometimes still in use by the conservative. In one agricultural district the wooden plough is still considered the only type suited to the soil; the old-fashioned Devonshire labourer sometimes carries his mid-day cider in a wooden firkin; in another remote district rare examples of the solid-wheel cart and old-fashioned wash-tub are carefully preserved. But whether now still in use or carefully preserved, sooner or later they will all be consigned to the dust-heap as the older generation and its memories die away, unless they are rescued by a kinder fate. Countless objects of priceless value for the study of English culture have vanished this way in the past; and unless some effort is made it will be too late to save even a part of what remains.

The spread of education and the standardisation of implements, utensils, and domestic appliances generally in modern industrial and economic conditions are tending with increasing rapidity to eliminate all that is individual and characteristic in the humbler arts and crafts. Especially is this the case with the rural dwelling with all that it can tell us of the past and in its local peculiarities—a very real product of its environment, eloquent of the different types of soil and landscape to be seen in England. These buildings, however, are rapidly disappearing before improved sanitation and the erection of model dwellings by local authorities as well as the urbanisation of the countryside. A folk museum would scarcely be fulfilling its function if it afforded an incentive to further work of destruction in order to provide housing for its collections. Unfortunately, there can be no question that ample provision will be made for its needs without any effort on its own part. Indeed, it should serve to save a few of the buildings which are now, or soon will be, condemned and beyond any other hope of preservation. Although the number of buildings of which the museum will be able to make use is limited, if only on account of space, it may yet serve on occasion to supplement the great work which is being done by the Royal Society of Arts for the preservation of characteristic dwelling-houses throughout the country.

Nor does it follow that the institution of a national museum should preclude the development of local folk museums and collections of folk-material. Indeed, the Anthropological Section, stimulated by Sir Henry Miers' account of what is being done in Sweden and elsewhere in this direction, urged the delegates of the corresponding societies of the British Association at Bristol to use their best endeavours to promote museums of this type in their respective localities.

Sir Henry Miers referred both specifically and by implication to the question of a site. Upon this

point much of considerable moment may be said. It is abundantly clear that a museum of the type suggested requires a considerable area for its effective display. The buildings cannot be dotted about indiscriminately all over the site. They should be arranged in something approaching the normal relation of buildings in an English village. On the other hand, any incongruity in period and style should be obviated by siting or by screening. The area available must therefore be considerable. A minimum of fourteen acres is suggested; but Skansen has sixty acres.

As regards situation, if the museum is to serve any effective scientific and educative purpose, obviously it must be readily accessible. It should be in or near some big centre of population. This immediately rules out such a suggestion as the Forest of Dean, which had something to be said in its favour on other grounds. Chiswick House has the advantage of being within easy reach of central London; but, unfortunately, the grounds are largely given up to sports and the amount of land available is inadequate. It has the additional disadvantage that the buildings in which a part of the collections would have to be displayed are very definitely 'period' buildings and of a type which would be incongruous with a folk collection.

It is generally agreed that London is the most appropriate centre for an English national museum, but here, if Chiswick House be ruled out for reasons mentioned above, at present only two proposals have come under consideration. Of these, one is that a site should be obtained adjacent to the Zoological Society's new grounds at Whipsnade. The distance—some thirty miles from London—is not so great an objection as might at first be thought. With the improved facilities for transport which are promised, Whipsnade will not be difficult of access. Further, the folk museum might count on the visits of a considerable proportion of those who come to the Zoological Society's grounds. Apart from the setting it would provide, however, Whipsnade cannot vie with the advantages of the grounds in Regent's Park. The area of the Royal Botanic Society's site is eighteen acres, and greater than could be obtained at Whipsnade except at a prohibitive cost; St. John's Lodge, a fine house adjoining, is available for purposes of the smaller exhibits and administration, and provision could be made for the continuation of the research work which is now being carried on in the gardens. If Mr. Lansbury's desire is that the Royal parks should be of lasting benefit to the population at large, could any purpose more fitting be found than a museum of the people for the people?

Quantum Theory.

IT is now five years since Heisenberg made the great advance in atomic theory by the introduction of non-commutative algebra, and a few months less since Schrödinger gave the mathematical form to the undulatory conceptions of de Broglie. At first the progress was so rapid that if anyone had been rash enough to compose a book, it would have been obsolete before it was in type, but during the last year or so there has been a lull in the developments. The consequence is a whole crop of books written by a number of authorities on the subject, some of which are reviewed here.

Before describing the details of these works, it is of some interest to consider what different types of presentation are possible. There is first the historical. This is probably the easiest to write, since the succession of the discoveries must always provide a possible order of treatment, even though it may later turn out to have been an illogical one; it is also a form that is acceptable to those who have themselves lived through the developments, since it serves to give them pleasant reminiscences of dead theories. On the other hand, there is a suggestion in this treatment of what we may read in many industrial reports, that " much capital has been sunk in the present process, and the directors do not consider that it would be profitable to scrap the existing machinery, even though more economical processes are already in existence ". The historical method also has the disadvantage of tending to upset the proportions. If it is followed here, it suggests that the quantum mechanics is a small addendum to the theory of spectra, whereas in fact the theory of spectra should occupy about the same position in quantum mechanics that planetary theory does in ordinary mechanics.

For the next generation there can be little doubt that it is no longer profitable to follow the historical method closely. What is wanted is something like the dynamical text-books, which enunciate the laws of Newton, without preceding them by an elaborate explanation of Galileo's experiments. There are still two choices open, according to where in the theory the emphasis is placed, whether on waves or on particles. This is a matter of taste, not of logic, and there will probably always be adherents of both sides. But we may perhaps discriminate between the tastes by an analogy from dynamics. Do we regard as the ultimate fact of dynamics that a particle's acceleration is proportional to the applied force, or that a dynamical system is a continually unfolding infinitesimal contact transformation? This is certainly an exaggeration of the distinction (and is perhaps a confession of partisanship on the part of the reviewer), but some writers do appear content to work out the relation of the new mechanics to classical Hamiltonian dynamics and leave it at that, whereas others make the attempt to get down to more primitive principles like those of Newton. Since atomic dynamics ought to be more primitive than molar dynamics, this last would seem to be the right policy, and the chief objection against it is that Newton's First Law must be replaced by a law expressing diffraction, rather a sophisticated idea to take as an axiom. So all we can say is that Nature itself offers us as starting-point the choice between two sophisticated ideas, that of diffraction and that of non-commutative multiplication, and everyone must choose for himself which he prefers.

(1) and (2) are respectively the French and German editions of the work of L. de Broglie, and they naturally follow the line of his own work and place the emphasis on the waves. The book begins with his well-known relativistic arguments and then passes on to Hamilton's association of dynamics with optics. There is then a good description of the general characters of waves, leading up to Schrödinger's equation. A special feature is the detailed working out of the separate behaviour of amplitude and phase, a separation that is not of much use in the actual discussion of problems, but helps in explaining the relation of the new mechanics to the old. The book then deals with electron diffraction and so proceeds to more complicated problems. A few actual cases are solved, but for the most part the work is devoted to an explanation of principles, including criticisms of those which have been tried and found wanting. The index shows that there are only two references to the word matrix—truly a striking difference from some of the other books under review. A novice would scarcely be able to start work on quantum problems without supplementing the present work by other reading, but he will gain insight into the wave aspects, and this will be a great help to him in getting a true, and not merely a technical, understanding of the subject.

(3) is a collection of five articles and addresses by the same author. They are of a semi-popular character, and are a pleasant and instructive exposition of his general outlook on the foundations of atomic physics.

(4) The work by Condon and Morse is much more of a text-book. It has the admirable quality of making the subject look simple and straightforward, and does not, like many other works, envelop it in an air of subtle mystery. After a general introduction it establishes Schrödinger's equation and works out a large number of examples connected with the spectra of atoms and molecules. Towards the end it explains the conceptions associated with matrices; this part is perhaps not quite so satisfactory, as it presents the theory in an earlier form and one which has not been found the best. We may also make another small criticism; it is rather surprising to find electron diffraction discussed in the very last pages of the book instead of the first. But these are minor defects, and, on the principle that the

learner wants much practice rather than much philosophy, the book can be strongly recommended as one which will give a very good working knowledge of the quantum theory.

(5) is a sequel to Born's well-known book on atomic mechanics. As such it is naturally concerned with the modifications of classical dynamics necessary in order to include the quantum theory, and indeed there is no mention at all of the wave equations. As an essay in how far can be gone without the use of partial differential equations it is brilliant, and contains full discussions of many problems which have not been given elsewhere, but as an exposition of the content of the quantum theory it must be judged a failure. We may even quarrel with the first word on the title-page, for to call the work "*Elementare* Quantenmechanik" is to give a very exaggerated idea of the difficulty of the other branches of the subject. The self-denying ordinance which has excluded wave equations severely limits the book's scope, for all continuous spectra are barred, and even the radial quantisation of the hydrogen atom is a very troublesome business, which can only be done by Pauli's method, a brilliant piece of work but one which can safely now be forgotten. In short, the only atomic problems that can be treated really well are those depending on the principle of angular momentum. But the book is to be followed by another part in which the wave methods are to be developed; this should redress the balance, and we can only regret that the two distinguished authors could not have issued both volumes together.

(6) is the French translation of Birtwistle's well-known book, which has already been noticed in the columns of NATURE (Oct. 6, 1928, p. 527). There are four appendices, added by the translators, on such things as the magnetic electron and the theory of metals.

(7) Prof. E. Bloch has issued in book form an excellent series of lectures on recent physics. It follows the historical sequence and traverses the whole field of recent experiments and theories, photoelectric effect, radiation, periodic table, and so on. It then turns to the new mechanics and covers the whole subject, again in historical sequence. It does not go so deeply into the matter as do the works previously noticed, but in view of the considerable space devoted to the description of experiments, that was not to be expected. It makes an admirable introduction to the whole of atomic physics.

(8) Messrs. Ruark and Urey's book, as its title implies, has a rather different purpose. Whereas the others stand for a new general dynamics, this is like a new astronomical dynamics, because its central interest is the structure of atoms and spectra. Two-thirds of the book is concerned with the old quantum theory, which still remains the most convenient way of summarising atomic structure, especially now that it is quite free from the confusion that used to arise in connexion with the exact values of some of the quantum numbers. This is excellent, and the only regret we may feel is that the authors could not find room for such things as a fuller description of Hund's theory of the ground states of atoms. The last part of the book is devoted to the new mechanics, and though it is perfectly sound it seems a little out of place; it is almost as though the Hamiltonian transformation theory were first introduced as an appendix to a book on the planets. But no doubt something of the kind was inevitable, for at the time of writing there was no book available from which this part of the argument could be quoted.

It will be seen that the new orientation of our physical ideas has led to a great variety of opinions as to what are the most important parts of the theory. There is no reviewer whose personal opinion would agree with all of them, but nevertheless they are all to be welcomed. Only so, by a synthesis of the conflicting opinions, can we hope to arrive at a universally acceptable view of the new dynamics. C. G. D.

More Antarctic Meteorology.

British Antarctic Expedition, 1907–1909. Reports on the Scientific Investigations. Meteorology. By Dr. Edward Kitson. Pp. 188. (Melbourne: Council for Scientific and Industrial Research; London: Official Secretary, Australia House, n.d.) 8*s*.

THE Australian Department of Scientific and Industrial Research has earned the thanks of the scientific world for its action in rescuing, discussing, and publishing the meteorological results of Sir Ernest Shackleton's Antarctic Expedition of 1907–9. The Department was led to this good deed by the report of a committee in 1927 to the effect that "first-class scientific work by Australian investigators was sometimes in danger of being lost to subsequent workers owing to the impossibility of securing its publication". Why the records kept so conscientiously and so laboriously on the *Nimrod*, at Cape Royds, and on the magnetic pole and south pole journeys, have hitherto remained undivulged (save for brief summaries in "The Heart of the

Antarctic"), is not clearly explained. They appear to have been left in Australia or New Zealand on the return of the expedition, and we are glad that the participation as observers of Shackleton's Australian associates has made it possible for their government at last to publish the results. We are grateful to Sir Edgeworth David, of Sydney, and to Sir Joseph Kinsey, of Christchurch, N.Z., for their acknowledged share in enabling Dr. Kitson to prepare the observations for publication and to show the bearing of the expedition's results on the meteorology of the Antarctic region and of the southern hemisphere.

This Dr. Kitson has done with the skill and care to be expected from the director of the New Zealand Meteorological Service, equipped as he is for the task by a lifelong experience of Australian meteorology. The delay of twenty years in publication deprived Dr. G. C. Simpson of much important information which would have facilitated his great work on the meteorology of Scott's last expedition; but, on the other hand, it has enabled Dr. Kitson to make use of that work and of the labours of Meinardus on the observations of the *Gauss* expedition, thus focusing attention on the problems dealt with by those masters of meteorology.

The period covered by the observations at the land station at Cape Royds on M'Murdo Sound was from March 1908 to February 1909, midway in time between the *Discovery* and the *Terra Nova* expeditions in the same region. The data are set forth in tables of hourly value of temperature and two-hourly values of pressure, wind, and clouds. Temperatures are given to whole degrees Fahrenheit, a sensible saving of space, for fractions of a degree are meaningless on spirit thermometers read in the conditions of Antarctic observing. Humidity observations, accumulated hourly with infinite trouble, have only been summarised in monthly means, the manifold uncertainties of wet-bulb readings below the freezing point not justifying the labour of detailed discussion.

It was natural for Dr. Kitson to discuss his results with particular reference to Dr. Simpson's great memoir, and the new data have suggested more than a few frank criticisms of the earlier discussion, to some of which there may possibly be occasion for rejoinders. Dr. Kitson considers that his data throw doubt on the reality of the diurnal variation of temperature in the winter months detected by Simpson. It appears also that Scott's station at Cape Evans was less influenced in its minimum temperature by the 'cold layer' than the *Discovery* winter quarters thirteen miles farther south, or Shackleton's station at Cape Royds six miles farther north, a somewhat surprising result which is explained by the position of the Cape Evans thermometer screen on a slight elevation. Dr. Kitson brings out the fact that the cold layer of air streaming off the Barrier and down the mountain slopes was more pronounced on the surface of M'Murdo Sound, even when free from ice, than at the shore station where turbulence caused by the descent of cold air from the slopes of Mt. Erebus produced mixture and so raised the temperature.

Dr. Kitson's main contribution to Antarctic meteorology seems to be the elucidation of the phenomena of the cold layer and the katabatic winds associated with it. He recognises the power of chilling by radiation and by contact with a cold ice-surface to produce a layer of intensely cold air on the Barrier or on large ice-floes fed by the descent of cold air from the Plateau under the influence of gravity. He does not, however, see in this action so dominant a factor in the general circulation of the atmosphere as Prof. Hobbs claims for it, or as Sir Napier Shaw is willing to concede. He inclines to the belief that this cold layer remains apart from the system of air circulation produced by balanced forces. He considers that the polar anticyclone, if such a term is applicable, is confined to the cold layer, which he thinks can never exceed a kilometre in thickness, and that above it there is a polar cyclone playing its full part in the normal circulation of the earth's atmosphere. This is very like the old view put forward and upheld by Buchan on the basis of his Ben Nevis discussions, that every sea-level anticyclone has a cyclone riding on its back.

Dr. Kitson lays stress on the parallelism of the Antarctic pressure waves with the sequence of pressure changes in Australia, suggesting a close relationship between the two. In his discussion of the general problem of southern hemisphere meteorology he travels somewhat far from Cape Royds and the *Nimrod* and lands himself in the rather dazzling region of sunspot cycles.

Dr. Kitson urges the importance of establishing permanent meteorological stations on the Antarctic continent, as the variability of climate from one year to another is greater there than in temperate regions and a long series of observations is necessary in order to arrive at normal conditions. On the other hand, he wisely deprecates the somewhat rash assertions that have been made by the promoters of Antarctic expeditions (not, we believe, by meteorologists and geographers as he implies) that results of practical importance to temperate countries will immediately follow the establishment of meteorological observations in the Polar regions.

All climate, he recognises, is due ultimately to the circulatory movements of the atmosphere as a whole, and every addition to our knowledge of the whole must increase our knowledge of every part. To this extent and no further can the establishment of new stations in the Antarctic be of practical benefit to humanity.

When the results of the Byrd expedition are available, and the long-looked-for observations on the *Endurance* in the Weddell Sea are made public, there will be a mass of Antarctic meteorological data which may be worth the while of a meteorologist of the first rank to discuss on its merits, without worrying about the views of earlier investigators or endeavouring to penetrate the precise meaning which they have locked up in such terms as wave, stroph, cyclone, and anticyclone.

Hugh Robert Mill.

A Chemical Engine.

Die chemischen Vorgänge im Muskel: und ihr Zusammenhang mit Arbeitsleistung und Wärmebildung. Von Prof. Otto Meyerhof. (Monographien aus dem Gesamtgebiet der Physiologie der Pflanzen und der Tiere, Band 22.) Pp. xiv+350. (Berlin: Julius Springer, 1930). 28 gold marks.

In the course of evolution, animals have had to solve some exceedingly difficult problems of engineering; one of them, perhaps the most fascinating for us to study, was the elaboration of an internal combustion engine, made chiefly of water, working isothermally and without serious deviations from neutrality. The only ultimate source of energy in this world is the solar radiation, but the higher animals avoid part of the problem by utilising the energy stored in the organic compounds which the plants synthesise with the aid of the sun's radiation. For these animals, therefore, the problem is to convert the potential chemical energy of the food into useful mechanical energy in the limbs. The engine which does it is the skeletal muscle. It is not difficult to obtain mechanical energy from a fuel, given adequate oxygen—even man can do it—but muscle has a further remarkable property: even though it depends ultimately on an oxygen supply, it can work without oxygen for a considerable time. The sartorius muscle of a frog may be isolated and kept in pure nitrogen: it will then perform enough work to lift itself to the top of a mountain before it is exhausted. How is this done?

Prof. Meyerhof's book contains the answer, so far as we know it, in 318 pages of small print; and it is a matter for congratulation that he has managed, by skilful division and subdivision of the subject, to do it in so short a compass. For this is no elementary bird's-eye view, but a detailed account of the present position. The book contains ten divisions dealing with such aspects as respiration, metabolism, the chemical phenomena of activity in relation to the thermal and to the mechanical phenomena. Each of these is subdivided and again subdivided. Thus we find the topic of lactic acid production by minced muscles from added carbohydrates dealt with under III.*B*.1.*b*., and the relation between phosphagen breakdown in activity and the chronaxie of the muscle under II.*D*.3.c. Section II.*A*.2.*a*.*α*. deals with the dissociation constants of the hexosephosphoric esters. The list of contents is classified in corresponding detail. This arrangement, backed by an 8-page subject index, makes the book an excellent work of reference; yet this is accomplished without sacrifice of interest, for despite the detailed 'cataloguing' the text reads quite continuously. Matters of historical interest are referred to where they are appropriate, but no attempt has been made to give the full history of the subject.

The last four years have been particularly rich in discoveries in this field: facts have accumulated sufficient to overthrow the theories current in 1926, but insufficient to form the basis of new ones. Lactacidogen is gone: it turned out to be pyrophosphate. Most of the 'inorganic' phosphate of muscle is now known to be organic. Moderate activity in the absence of oxygen no longer makes a muscle acid—it now becomes alkaline or does not change at all. Lactic acid no longer initiates contraction; for a muscle may give twitch after twitch in nitrogen without any lactic acid accumulating. True, the muscle has been poisoned with iodoacetic acid, but it is not to be supposed that the muscle has invented a brand-new mechanism on the spur of the moment. The situation disclosed by Prof. Meyerhof in this book is indeed chaotic.

A considerable proportion of Prof. Meyerhof's theoretical treatment of the subject deals with the origin of the 370-400 calories of heat which accompany the formation of each gram of lactic acid in the muscle, and here we are moved to voice a protest. The heat of formation of lactic acid from glycogen in dilute aqueous solution may be calculated from the measurements of different workers, and it comes out to anything from 180 to 235 calories per gram of lactic acid. The uncertainty is chiefly due to the discrepant values for the heat of combustion of glycogen. The heat of neutralisation of lactic acid may be anything from 20 to 140

calories according as we use buffer salts or proteins for the neutralisation. Thus the combined heat of the two reactions may be anything from 200 to 375 calories—anything from one-half to the entire heat actually observed to accompany the process in muscle. For reasons which he gives in the text, Prof. Meyerhof takes the value 290 calories, but we feel that no amount of logic will compensate for uncertainty in the primary measurements.

The text includes 26 tables and 66 diagrams. The printing is well done, on good paper, but the binding is bad. There are two bibliographies; one contains 125 references to work performed in the author's laboratory, and the second contains 296 references to other work. There exists at the moment no treatise on muscle chemistry, in any language, so complete and up-to-date as this book.

Philip Eggleton.

Our Bookshelf.

Annales de l'Institut Henri Poincaré: recueil de conférences et mémoires de calcul des probabilités et physique théorique. Vol. 1, Fasc. 1. Pp. 74. (Paris: Les Presses Universitaires de France, 1930.) 35 francs.

The Henri Poincaré Institute invites leading scientific workers to lecture on recent progress in mathematical physics. The "Annales", of which the first number has just appeared, will contain a French translation of these lectures. In the present number we have Einstein on the unitary field theory, C. G. Darwin on the wave theory of matter, and Fermi on the theory of radiation.

Einstein's lecture is addressed to mathematicians, in the hope of interesting them in a theory as yet very incomplete, but offering magnificent possibilities of development. He cannot account for certain identities that he has discovered, and he appeals to geometers to come to his aid. There is no possibility of verifying the theory by experiment until a certain mathematical problem has been solved.

Problems in quantum theory can be treated by the wave mechanics of de Broglie and Schrödinger, or by more abstract methods based upon the general theorems of analytical dynamics. Darwin considers that wave methods have the advantage of enabling one to deal intuitively with phenomena too complicated for mathematical treatment. The object of his lecture is the development of this intuitive power.

In the third lecture, Fermi shows how a uniform method can be applied to problems of interference and of the Compton effect, of which the first set are usually treated by classical methods and the second by quantum mechanics. The starting-point is Dirac's concept of the atom and radiation as forming a single system, the energy of which is the sum of three terms, due respectively to the atom alone, to the electromagnetic field, and to the interaction of the two.

Future issues will contain lectures by Born, Debye, de Donder, Kostitzin, Lévy, Pólya, and Volterra.

H. T. H. P.

The Magneto Manual: a Practical and General Reference Work for Automobile Engineers, Aeronautical Engineers, Mechanics, Apprentices, Chauffeurs, Car-Owners, etc. By H. R. Langman. (Lockwood's Manuals.) Second edition enlarged. Pp. xii + 246. (London: Crosby Lockwood and Son, 1930.) 7*s.* 6*d.* net.

In many internal combustion engines the ignition of the explosive mixture is effected by means of an electric spark which is produced by a small machine called a magneto. The great demand for these machines for motor and aero engines has led to a very close study of the principles on which they work, and this has resulted in great improvements in their design. This book will prove useful to all engaged in motor engineering. The author wisely does not describe the functioning of any particular type of magneto, but confines himself to general remarks and a description of the outstanding features of the best types in everyday use. The trend of invention and industrial activity is in the direction of perfecting old types rather than the introduction of new types. In this edition a useful chapter has been added which gives a simple description of the theory of the high tension magneto. Many sketches are given depicting common faults. These should prove a help to driver owners of cars in maintaining their magnetos in good working order. The neon gas spark tester, the working of which depends on the low electric strength of neon, is described

Metalliferous Mine Surveying. By Thomas G. Hanton. Pp. xii + 224. (London: Crosby Lockwood and Son, 1930.) 15*s.* net.

The fundamental problem in mine surveying is the connexion between the surface and underground surveys and their relations to the boundaries of the property. In this book, which, unfortunately, the author did not live to see published, a successful effort has been made to present clearly and accurately modern methods of mine surveying with special reference to the correlation of the various parts of the work involved. Careful and practical descriptions of the instruments used are given, followed by details of survey practice and methods of preparing plans and sections and written records. Later chapters deal with stope surveys, estimation of ore reserves, and borehole surveying. The whole treatment is well proportioned, clearly written, effectively illustrated, and copiously provided with examples and calculations. Colliery surveying is not specifically dealt with, but the metalliferous mine surveyor has here a thoroughly up-to-date guide to all the leading features of his varied profession. The work was written by an Australian surveyor who had a wide experience, and his book represents the successful accomplishment of a difficult task.

The Micelle Structure of the Wool Fibre.

THE real existence within the wool fibre of micelles which are impervious to water molecules and dyestuffs has only occasionally been suggested[1] and never demonstrated. Two independent lines of investigation have recently converged, not only to prove the existence of micelles, but also to give some idea of their shape and dimensions, and the manner of attack by certain reagents. In an earlier paper,[2] I was able to show that the size of the capillary spaces in the dry wool fibre is of the same order as the length of the *n* propyl alcohol molecule. Whereas wool fibres in methyl alcohol and ethylene glycol are easily extensible, in butyl and amyl alcohols they resist extension to a degree closely similar to that of the perfectly dry fibre. When, however, the higher alcohols are mixed with methyl alcohol or ethylene glycol, these latter reagents enter the fibre and cause it to swell, opening the pores until they are able to admit the larger molecules. This is well illustrated by a comparison of the properties of wool fibres in octyl alcohol, ethylene glycol, and mixtures of the two. The potential energy necessary to extend fibres 30 per cent of their length in the various media at 22·2° C. was determined and typical results are quoted below:

Medium.	Potential Energy (gm.cm per c.c.)
Octyl alcohol	$5{\cdot}17\times10^5$
Ethylene glycol	1·63 ,,
Ethylene glycol-octyl alcohol	1·72 ,,

The molecular concentration of ethylene glycol in the above mixture with octyl alcohol was only 60·8 per cent, and since the properties of the fibre in the mixture are almost identical with those in ethylene glycol alone, it seems clear that the pores of the swollen fibre are sufficiently large to admit the octyl alcohol molecule. This great increase in pore size is in striking contrast with the small increase in the over-all dimensions of the fibre. Swelling is greatest in water, but even in this case the increase in length of the dry fibre is only 1·1 per cent and the increase in diameter about 18 per cent. The co-existence of a large increase in pore size with a small increase in cross-sectional area affords a critical proof of the existence within the fibre of micelles which are relatively, if not entirely, impervious to molecules as small as the water molecule.

It has been found possible to extend the preceding argument to give a measure of the thickness of the micelles. Determinations of the potential energy required to stretch fibres were made in a series of mixtures of methyl- and octyl-alcohols. In the region of low concentration of methyl alcohol, the work required to stretch fibres at first decreased slowly with increasing concentration of methyl alcohol, as would be expected by analogy with the properties of wool fibres in atmospheres at various relative humidities. When, however, the concentration of methyl alcohol was great enough to produce a sufficient degree of swelling, octyl alcohol molecules could gain admission to the fibre, causing an immediate fall in the resistance to extension. Determinations of the increase in diameter of wool fibres in the critical mixture required to admit octyl alcohol, combined with the fact that the pore size must have been increased by the difference between the lengths of the *n*-propyl alcohol and octyl alcohol molecules, indicate that the thickness of the micelles must be of the order of 200 A. Knowing the increase in diameter of wool fibres in water, and making use of the preceding determination of micellar thickness, it can be shown that the pore size in fibres swollen in water is of the order of 40 A.

From a comparison of the changes in the elastic properties and size characteristics of wool fibres with water adsorption, I have previously deduced[1] that the micelles must be long in comparison with their thickness. Discrimination between the possible shapes which will fulfil this requirement was made possible from observations on the affinity of sodium sulphide treated wools for water. Known weights of purified Cotswold wool were treated with sodium sulphide solution for different times, the loss in weight being in each case ascertained after removing adsorbed sodium compounds by prolonged washing in distilled water. The amounts of water adsorbed by the dry, treated and untreated, wools were then determined at various humidities. A few typical results are given in the following table, the different wools being distinguished by indicating their loss in weight after reaction with sodium sulphide:

Relative Humidity. %	Percentage by Weight of Water adsorbed by			
	Untreated Wool.	Sodium Sulphide treated Wools.		
		13·0% loss.	46·0% loss.	56·7% loss.
24·2	6·80	6·77	6·75	6·93
73·5	17·00	16·82	16·94	17·24
91·3	24·83	24·75	26·01	25·47

It is a highly significant fact that wool treated with sodium sulphide until the loss in weight is as high as 57 per cent should show almost exactly the same affinity for water as untreated wool. In view of the proved existence of micelles which are impervious to water, there can be only one possible explanation of the results: that the ratio of surface to mass remains unaltered with loss in weight. Combining this requirement with those indicated above, it becomes clear that the most probable shape of the micelles is the lamella, and that attack by sodium sulphide is largely confined to the edges, leaving the surface mass ratio sensibly unaltered. In addition, these observations indicate that the disulphide link in wool, which is the point of attack by sodium sulphide, must lie in a plane making an obtuse angle with the large faces of the micelles. Finally, there is now an obvious explanation of Marriott's[3] observation that treatment of hair with sodium sulphide until it shows a 26 per cent loss in weight leaves the ratio of the nitrogen and sulphur contents unaltered.

Hyperfine Structure in Some Spectral Lines from Highly Ionised Atoms of Thallium and Bismuth.

IN working with spectra in the extreme ultra-violet at the physical laboratory in Uppsala, I have been able to observe a hyperfine structure in some spectral lines in the region 1400-800 A. The lines investigated are due to higher ionisation stages of thallium and bismuth. For thallium, hyperfine structure has been measured before in the arc spectrum and in the first spark spectrum, and for bismuth, in the arc spectrum.

The lines now observed have in some cases much larger wave-number differences than any before measured.

The spectrograph is of the same type as two others designed by Prof. Siegbahn and described in other places.[1] It has a concave speculum grating with a radius of 1·5 m. and 1060 lines/mm.

The method with grazing incidence is used, and the angle of incidence is about 7°. The dispersion at 800 A. is 2·6 and at 1400 A. 3·4 A./mm.

The spectrograph has a volume of about 30 lit. and the vacuum is obtained by two Siegbahn molecular pumps in parallel backed by an oil-pump. As light source is used a condensed spark with a condensor of about 0·3 μF in parallel with the spark. The charging current for the condensers is rectified by a kenotron.

It is possible to measure these small separations only when narrow lines of the proper intensity are obtained. It is, therefore, necessary to work with a very narrow slit and use different exposures for different lines.

The possible errors in wave-length differences are estimated to about 0·01 A., which corresponds to 1 cm.$^{-1}$ in wave-number.

Table I. gives the separations of some previous classified lines in Tl III[2] and Tl IV.[3] Some of these

The values of the wave-lengths are from Carrol's[6] measurements.

lines are seen on the magnified plates reproduced in Fig. 1.

The separation measured for the level 6 $^2S_{\frac{1}{2}}$ of Tl III is 6·4 cm.$^{-1}$. From the spectrum of Tl II,

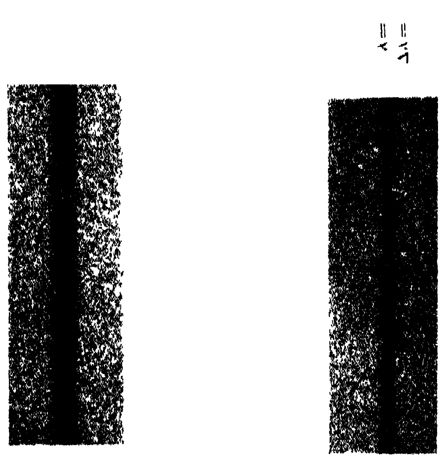

FIG. 1.—Thallium. Magnified 54 times.

Bacher and Goudsmit[4] have calculated a value between 7 and 8 for this level.

Table II. and Fig. 2 give the separations of four lines in the spectrum of bismuth: two doublets and two triplets. The two triplets are classified by Lang[5] in the way given in the table as belonging to Bi III. With respect to the fine structure, it would be very strange if this classification should prove to be correct.

According to Bacher and Goudsmit's theory, if the

		0·099	5·7	

The wave-lengths are calculated from reference lines of oxygen, nitrogen, and carbon.

splitting of the triplet is due to one level only, it must have $j = 1$. Since the nucleus quantum number $I = 4\frac{1}{2}$, for bismuth, then the resultant $F = 3\frac{1}{2}, 4\frac{1}{2}, 5\frac{1}{2}$. The ratio of the separations in the triplets would be expected to be 11/9 = 1·22.

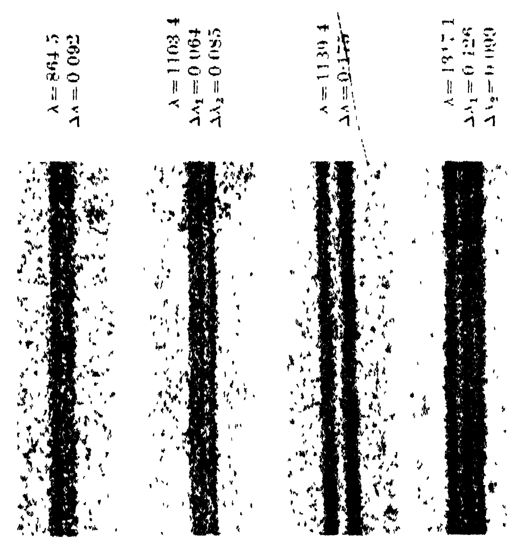

FIG. 2.—Bismuth. Magnified 51 times.

For the measured triplets the ratios are 1·32 and 1·28, and the separations within the errors of measurement are the same, though the larger separation for one is toward long, and for the other toward short wave-lengths. One would then expect them to correspond to transitions between 6 s 6 p $^3P_1$[(6 s 6 $p_{\frac{1}{2}}$)$_1$, Goudsmit's notation] and a more stable term 6 s^2 $^1S_0$ and a less stable term, for example, 6 s 7 s $^1S_0$ or 6 p^2 term.

It can be expected that the possibility of measuring the hyperfine structure in these regions will prove to be a good tool for classifying spectra from some highly ionised heavy atoms. This aid is much needed. In general, lines from many different stages of ionisation are mixed together and the possible error in wave-number increases rapidly as the wave-length decreases.

Rate of Growth of the Common Starfish, *Asterias rubens*.

IN the course of a study of the growths on the buoys and beacons in Liverpool Bay marking the entrance to the Mersey Estuary, young *Asterias rubens* have in nearly all cases been found clinging to the undersides of those structures. There is no doubt that these starfishes have settled as larvæ in this position and have grown *in situ* by feeding on coexisting mussels (*Mytilus edulis*), which have always been found in abundance. As definite observations on the rate of growth of the common starfish are necessarily rare and difficult to obtain, the following are of interest.

On May 30, 1930, the black beacon *Q*7 from the Queen's Channel was dry-docked and examined, and found to be carrying a large number of young *Asterias rubens*. About 1800 of these were collected, preserved in the laboratory, and afterwards measured to give the graph shown in Fig. 1. The measurement adopted

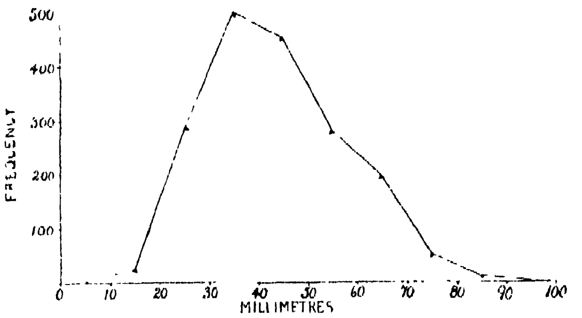

FIG. 1. Size-frequency in 10 mm. groups of 1800 *Asterias rubens* (aged not more than 1 year) from the black beacon *Q*7, Queen's Channel, Liverpool Bay, May 30, 1930.

to give a criterion of size is the length of the straight line joining the tips of alternate arms. The modal value in Fig. 1 is nearly 4·0 cm., while size ranges between 7 mm. and 9·4 cm., and the mean value is 4·2 cm. In life these specimens would measure in repose about 5 mm. more on the average. As the buoy *Q*7 was placed on station on April 3, 1929, the greatest age of these *Asterias* is about 13 months. The actual age is, however, rather less. Post-larval *Asterias* of only a few millimetres were obtained in 1930 on a buoy (*C*8 black) on July 25—and rather larger sizes in great quantities on other buoys at a later date—thereby proving that settlement occurs in this stage and giving also an indication of the date of settlement.

If post-larvæ be assumed to settle in general on buoys from about June onwards, then it is seen that a population of *Asterias* may attain a maximum size of about 10 cm. and a mean of 4·5 cm. in less than one year. But as *Asterias* probably spawns round about April in this locality, the actual age (from the time of fertilisation) of these small starfishes is approximately one year. It is an extremely interesting fact that minute post-larval *Mytilus* were obtained on another buoy (*Q*3 black) on June 27, 1930, at just about the right time to serve as food for the growing baby *Asterias*. The latter have not been observed actually eating the post-larval mussels, but there can be little doubt that this is the source of their sustenance. Young mussels were probably also largely the food of *Echinus miliaris* taken from the bottom of the Bar lightship along with 15 cm. *Asterias rubens*, large mussels, medium *Actinoloba dianthus* and other forms, also on June 27, 1930. These *Echinus*, it may be noted, were mostly the long-spined variety, and were similar in this respect and in size to those obtained on the coal hulk *London City* (see NATURE, 111, p. 146; 1923). As these sea-urchins could only attain access to the bottom of ships by the settlement of larval forms, and as this lightship was put out on Nov. 22, 1927, their age, as well as that of the larger *Asterias*, is not more than two years.

We are greatly indebted to Capt. Mace and Mr. A. L. Hulme, of the Mersey Docks and Harbour Board, who kindly supplied information regarding the records of the buoys mentioned above.

Depreciated Morphology.

IN a recent review (NATURE, Sept. 6, p. 341), Prof. Elliot Smith reproves at some length an anonymous group of contemporary biologists whose attitude towards morphology is one of ill-concealed contempt. Escaping the discipline which alone attends the laborious drudgery of morphological research, they pour contempt on that field of biology which, in the past, has yielded all our richest fruits. Few biologists will read Prof. Elliot Smith's remarks unmoved. Some will learn, for the first time, that there is a race of upstarts - presumably experimental biologists - who not only ignore, but also despise, the foundations of their own beliefs. Others—perhaps no insignificant minority—will learn with dismay of the great gulf which protects the true morphologist from the taint of experimental corruption.

I venture to think that the picture is not quite so dark as Prof. Elliot Smith has painted it. Whether we use a macerating pot or an X-ray for the study of animal form, the goal remains the same—to show how the component parts of an animal (whether they be bones or molecules) are so shaped and so orientated to one another as to form a living organism capable of undergoing evolutionary change. To this end the morphologist (in the classical sense) has contributed, and is continuing to contribute, a more complete record of correlated facts than his younger colleagues in experimental laboratories can hope to do for many years to come. Nevertheless, the final goal will not be reached by those who restrict their conceptions of animal life to the facts revealed by a scalpel and a microtome, or by those who ignore all knowledge of the anatomical sciences. Until we can add to such facts as are described in Prof. Goodrich's distinguished volume a knowledge of the form and mechanism concealed within a muscle fibre and a gamete, the theories of the evolution of the vertebrate skeleton will necessarily remain vague and unsatisfying to certain types of mind.

Facts of real biological significance are drawn from an ever-widening field, and there is an inevitable tendency to specialise in apparently unrelated territories. To some extent this is inevitable, but whether we regard an organism as an intricate piece of molecular machinery or whether we prefer to examine the brain with a hand lens, it scarcely seems necessary to allow our predilection for one or other point of view to imply a negation or an implied criticism of the other. It is just as inconsistent to ignore the morphological significance of experimental data as it is to study the behaviour of an organism without reference to its form or evolutionary history. If experimental biologists are too fond of 'looping the loop', it is equally true that morphologists are not disinclined to creep about on all-fours.

It is to be hoped that experimental biology will never be regarded as the antithesis to morphology. There is no intrinsic virtue in experiment—it is solely an additional weapon of biological armament. The very name 'experimental' is a misnomer and might well be replaced by 'analytical', for this at least indicates an attitude of mind of those who attempt to analyse

living phenomena in terms of matter and energy, and who try to regard experiment and observation with strict impartiality. The only difference between such misguided folk and Prof. Elliot Smith's declining band of faithful warriors lies in the belief that the rich harvest of classical morphology would provide more palatable food, for the young, if leavened by a knowledge of physiological facts.

It is depressing to think that a study of living organisms inevitably entails severe morpholophobia and that the only cure is a return to the dead. In spite of anxious and widespread inquiry, I have failed to discover any genuine case of this unfortunate disease; perhaps it only affects the very, very young.

J. Gray.

King's College, Cambridge.

Ovoviviparity in Sea-Snakes.

Mr. Smedley's note on viviparity in the sea-snake (*Laticauda colubrina*) in Nature of Aug. 30, p. 312, needs some comment. My statement (which he quotes) that all sea-snakes are viviparous was not a reiteration of that of previous authors, but a confirmation, based upon personal knowledge of the group. In the light of fresh information, however, it requires some qualification.

The recent investigations of Miss Weekes have shown that true viviparity, with the formation of a placenta, first described in *Chalcides* by Giocomini in 1891, occurs in some Australian lizards (*Lygosoma* and *Tiliqua*) and snakes (*Denisonia*), and it would be well in future to restrict the term viviparous to those species in which some form of placentation can be shown to exist. Whether the sea-snakes are truly viviparous or not, is unknown, but that the majority of the species of the subfamily Hydrophiinæ produce their young alive is a well-established fact. All the members of that group are strictly aquatic in their habits and never seek the land, and no other form of reproduction therefore seems possible for them. With the *Laticaudinæ*, genera with broad ventral shields and partly terrestrial habits, it is different. I have recently examined a specimen of *Laticauda colubrina* with well-developed embryos enclosed in a thin semi-transparent covering, and also an example *Aipysurus eydouxi* with young less well developed and enclosed in a thicker capsule. From their position in the body of the mother it was evident that they were not yet ready for expulsion and that further development would have taken place before they were discharged. These species, therefore, appear to be ovoviviparous.

The eggs laid by Mr. Smedley's snake are no doubt similar to those deposited last month by the same species of snake in the Zoological Society's Gardens in London, and which are—in view of what has just been stated—eggs that have been prematurely laid in consequence of captivity. The fact that they were laid one by one at intervals of a few days, supports this conclusion.

Malcolm Smith.

London, Sept. 7.

Measurement of the Heaviside Layer Heights.

If the carrier wave of a wireless transmitter be increasing steadily in frequency, then a given receiving station will in general pick up two waves differing in frequency. One of these waves will have reached the receiver by the shortest path along the ground, while the other will arrive after having suffered reflection at the Heaviside layer. After rectification these two waves will give rise to a beat-note in the receiver. It is possible to arrange that this note shall have an audible pitch, and a determination of the latter may be used to obtain a measurement of the height of the layer. The resulting method possesses some advantages, such as simplicity, and is besides adapted to the obtaining of continuous records.

In practice, it is not possible to continue increasing the carrier frequency indefinitely, but this difficulty is overcome by alternately increasing and decreasing the frequency many times a second, the rate of increase being constant and equal to the rate of decrease. It is evident that, corresponding to the change over from increasing to decreasing frequency at the transmitter, there will occur at the receiver a short period during which the frequency of the beat-note decreases rapidly to zero and rises again to its former value. The duration of this period must be made small compared with the time during which the beat-note remains steady. This condition is satisfied in practice by ensuring that the time during which the carrier frequency is increasing (or decreasing) shall be large compared with the time difference of the two ray paths.

Preliminary tests of the method have been made, and an audible beat-note has been detected at a distance of seven miles from the transmitter, on a wavelength of 250 metres. The experiments are being continued with improved apparatus. The details of the method, and the results obtained, will be published elsewhere in due course. The work is being carried out under the auspices of the Radio Research Board of Australia.

The Spectrum of Trebly-Ionised Selenium.

The spectrum of selenium has been investigated (in Prof. Fowler's Laboratory at the Imperial College, in collaboration with Mr. J. S. Badami) from λ7000 to λ700, using different intensities of discharge, through capillary tubes containing selenium metal or the oxide. Between λ1400 and λ500 photographs have also been taken in this institute of the spark spectrum of selenium with a vacuum spectrograph designed by Prof. Siegbahn, having a grating of radius 150 cm., at tangential incidence. With the aid of these, the doublet system of trebly-ionised selenium, due to the configurations $4s^24p$, $4s^24d$, etc., and $4s4p^2$, has been identified. The characteristic separations are: $4p^2P_1 - 4p^2P_2 = 4378$; $5p^2P_1 - 5p^2P_2$ 1198; $4d^2D_2 - 4d^2D_3 = 389$, etc. Details of the analysis will be published shortly.

British Museum (Natural History): General and Departmental Libraries.

With reference to a review, appearing in the Supplement to Nature for Oct. 4, of the list of place-numbers of societies issuing serial publications contained in the General Library of the British Museum (Natural History), I have been desired to point out that this List, being a *General* Library List, does not include the more special serials housed in the five Departmental Libraries of the Museum. This would account for the list's apparent weakness in specific branches of natural science, so justly commented upon by your reviewer.

A. Cockburn Townsend
(Assistant-Keeper in charge of the General Library).

British Museum (Natural History),
London, S.W.7, Oct. 3.

The preface to the volume noticed does not contain any reference to the five Departmental Libraries; but I accept unreservedly Mr. Townsend's correction of my comments.

The Reviewer.

The Nitrogen Industry and our Food Supply.*

By Dr. R. E. Slade.

FOR many centuries nitrogen was used as a fertiliser in the form of farmyard manure, and certain rotations of crops, which kept up the nitrogen in the soil, had been popular; but it was not until 1840, when Liebig first pointed out the true function of nitrogen, potash, and phosphorus, that fertilising became an art based on science. Liebig's work became widely known in a very short time. A little later Lawes and Gilbert started their experiments at Rothamsted, which definitely proved the part taken by nitrogen in agriculture.

From 1840 the use of nitrogen in the form of Chile nitrate steadily increased, and about 1880 sulphate of ammonia became available from by-product coke ovens, and by 1903 the world consumption of these two fertilisers had increased to 1,975,000 tons, equivalent to 351,000 tons of nitrogen.

In 1905 calcium cyanamide was manufactured on a commercial scale for use as a fertiliser, and in the same year the arc process for combining the oxygen and nitrogen of the air to form nitric acid was launched unsuccessfully in Canada. Two years later the arc process was established in Norway and calcium nitrate was put on the market as a fertiliser. Thus Crookes's dream of the commercial production of nitrogenous fertilisers from the nitrogen of the air was realised in less than ten years. But it was the Haber-Bosch process for the fixation of nitrogen which was to supersede all others and make it possible for us to produce all the nitrogen fertilisers we require now and as far in the future as we can see. In 1906–9 Prof. Haber investigated the chemical equilibrium between nitrogen, hydrogen, and ammonia when heated under a pressure over a catalyst. Then Dr. Bosch of the Badisch Analin u. Soda Fabrik successfully manufactured ammonia on a large scale by this process in 1913 to 1914.

The fixation of nitrogen in the form of ammonia is so much cheaper than by any other process that this process has very largely replaced the cyanamide and arc processes, and it has shaken the Chile nitrate industry to its foundations—so that the Chilean Government and the nitrate manufacturers have to revise their methods and their processes.

The production of nitrogen in various forms is shown in Fig. 1. The quantities are expressed in tons of nitrogen contained in the products. It will be noticed that the nitrogen industry had already achieved considerable importance in 1898, but it was not until 1921 that the synthetic nitrogen production became greater than the Chilean nitrate production.

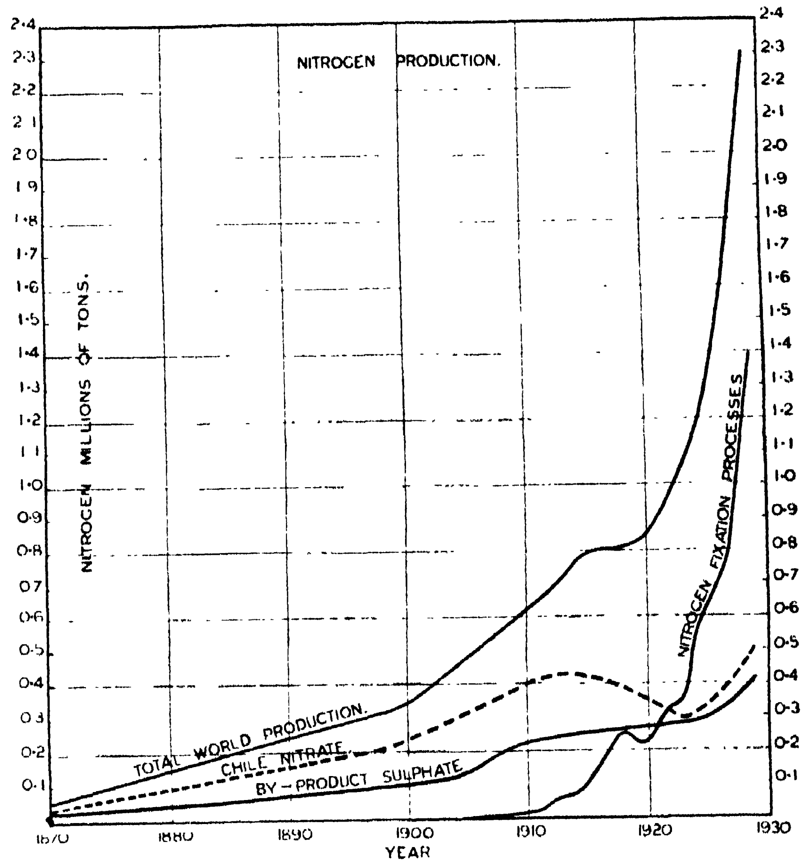

FIG. 1.

NITROGEN FERTILISERS.

The world's consumption in 1928 of nitrogen in the form of ammonium sulphate from synthetic ammonia and by-product coke ovens, cyanamide, nitrate of lime, nitro-chalk, and ammonia liquor was 1,442,000 tons and in the form of Chile nitrate 401,000 tons, making a total of 1,843,000 tons, of which 185,000 tons are used in industry and 1,658,000 tons are consumed as fertilisers. If fixed nitrogen is worth £50 a ton—which is about its price in sulphate of ammonia to-day—then the value of the nitrogen used in fertilising was £83,000,000.

Now, in an acre of typical English arable soil we have in the top nine inches a quantity of humus containing about 2500 lb. of nitrogen, and at certain times of the year changes take place in the soil making some of this nitrogen into nitrates, in which form it is available for absorption by the plant. The result of this is that in the spring about one per cent of the nitrogen in the humus is present

* From an evening discourse delivered at the meeting of the British Association at Bristol on Sept. 9.

in the form of nitrate; thus we have present about 25 lb. of nitrogen available for the plant. As this available nitrogen is used up by the plant it is partly replaced by more nitrate being formed from the humus, but during the time of greatest growth there is a considerable depletion of available nitrogen in the soil. Owing to the continuous breaking down of the humus, the nitrogen absorbed by the plant is often more than 25 lb., besides what is washed away by rain. The supply of available nitrogen may be increased by the addition of nitrates or ammonium salts—for the latter are rapidly oxidised to nitrates in the soil.

If we spread one hundredweight of sulphate of ammonia over an acre of ground, this adds 23 lb. of nitrogen to this area, or if we consider the top nine inches of the soil over this area of an acre, we add 1 lb. of nitrogen to each 120,000 lb. of soil. This is such a small amount that we might be doubtful whether it would be sufficient to make any appreciable difference to plants grown on this area. But we have seen that this quantity is of the same order as the quantity of available nitrogen already in the soil.

We will now inquire into the magnitude of the increased yields of crops which can be obtained by the use of nitrogen fertilisers. The figures given in Table I. are average increased yields of various crops obtained on good soil for the addition of each lb. of nitrogen in a fertiliser. They are the averages over many years and many different soils, so that they are the increased yields that may be expected for the addition of each lb. of nitrogen—if there is not a deficiency of potash or phosphoric acid in the soil.

Table I.

Crop.	Increase for 1 lb. Nitrogen. (lb.)	Nitrogen in Crop. (Per Cent.)	Efficiency. (Per Cent.)
Wheat (grain)	11·4	1·8	20·4
Barley (grain)	14·2	1·3	18·5
Oats (grain)	12·4	1·6	19·7
Potatoes (tubers)	94·0	0·3	28·2
Swedes (roots)	94·0	0·2	18·8
Mangolds (roots)	150·0	0·2	30·0
Hay	42·3	1·45	61·5

The nitrogen efficiency of the fertilisers in the last column is the percentage of the nitrogen in the fertilisers which appears in whole or part of the crop described in the first column.

In Table II. the increased yields are recalculated so as to show the increased crop obtained from one hundredweight of sulphate of ammonia in common units.

Table II.

Crop.	Increase for 1 cwt. of Sulphate of Ammonia.
Wheat	4·5 bushels or 2·41 cwt.
Barley	6·5 ,, or 3·02 ,,
Oats	7·0 ,, or 2·62 ,,
Potatoes	20·0 ,,
Swedes	20·0 ,,
Mangolds	32·0 ,,
Hay	9·0 ,,

If we feed grass to a cow giving two gallons of milk a day, we find that 1 lb. of nitrogen causes sufficient extra grass to grow to keep the cow alive one day and to give two gallons of milk. Since two gallons of milk contain 0·8 lb. of proteins or 0·128 lb. of nitrogen, we have 12·8 per cent of the nitrogen of the fertiliser appearing in the milk, or the efficiency with which the fertiliser is used via grass to make milk is 12·8 per cent.

The efficiency of meat production is lower, one pound of nitrogen fertiliser only producing 0·05 lb. of nitrogen in beef, or an efficiency of 5 per cent on the fertiliser.

Summing up these nitrogen efficiencies we have:

Fertiliser to grain	about	20 per cent.
potatoes	,,	30 ,, ,,
grass or hay	,,	60 ,, ,,
milk	,,	12·7 per cent.
beef	,,	5 per cent or lower.

It is not surprising that grass shows a higher efficiency than other crops, because the roots cover the ground more completely. I think that the efficiencies on the whole are very high; compare the energy efficiency of a high-class locomotive on the railways, which is not more than 8 per cent.

Food Production.

The food of a man in Great Britain is approximately:

Meat, fish	14·5 per cent.
Cereals	18·5 ,, ,,
Milk, cheese, etc.	24·5 ,, ,,
Potatoes and roots	25·8 ,, ,,
Sugar, fruit, etc.	15·5 ,, ,,

—and the nitrogen efficiency in growing these foods from fertilisers is probably about 17 per cent.

The amount of protein consumed per head is 86·5 gm. per day; this contains 14 gm. of nitrogen, so that if this food were grown by using fertilisers at an efficiency of 17 per cent we should require to use 82 gm. of nitrogen in fertilisers to produce the food for one person for one day; or the fertiliser required to feed one person for a year must contain 365 × 80 gm., or 29 kgm. of nitrogen. One ton of nitrogen in the form of sulphate of ammonia or nitrate of soda will therefore produce enough food for 34 people for one year.

Since the total amount of nitrogen consumed in fertilisers during 1928 was 1,658,000 tons, the amount of extra food produced from this fertiliser would contain enough nitrogen in the form of proteins to support 56,000,000 people; and there would be sufficient carbohydrates and fat associated with this protein to form a complete diet.

Sir Daniel Hall has shown that 2-2½ acres of land are required under cultivation to feed one person. Let us compare this with 1/34 tons of fixed nitrogen. If we assume that the total capital required to build a nitrogen factory is £70-£100 per ton year of nitrogen, inclusive of everything, then for a maximum of £3 invested we can support one person. It would be impossible to bring 2-2½ acres of land under cultivation at so low a capital cost. I do not think that land can usually be settled and cultivated at a less capital cost than £10 per acre, including roads and railways, houses, and agricultural machinery, so that to bring two and a half

acres under cultivation would need £25 capital as compared with £3 necessary to produce the fertiliser to produce the same amount of food. I would particularly like to direct attention to this calculation in some countries where governments are always ready to consider and finance schemes to build railways and roads to open up new country or to build irrigation schemes, although the capital to be invested for a given amount of food-producing capacity is often enormous.

STABILITY OF THE NITROGEN FIXATION INDUSTRY.

In fixing one ton of nitrogen and making it into fertilisers we use for all purposes about five and a half tons of coal, so that to provide the fertiliser to feed one person for a year we require $3\frac{1}{4}$ cwt. of coal. The population of the world (excluding China and Turkey) is now about 1940 millions, and 56 millions or 2·8 per cent are now being fed with food grown by nitrogen fertilisers. Of the nitrogen fertilisers consumed in the year 1928, about 1,000,000 tons of nitrogen was produced by synthesis, needing 5·5 million tons of coal. This quantity of coal is almost negligible when compared with 1500 million tons mined every year. The rest of the nitrogen was produced by by-product coke ovens or as nitrate of soda from Chile.

The population of the world increased by 10 millions each year from 1913 to 1928. If we had to feed this increase of population by increased nitrogen fertilisation, we should have to build each year a works which would fix 300,000 tons of nitrogen per year and would cost upwards of £30,000,000. In order to run the works we should require 1·6 million tons of coal per year. If we built a works of this size every year for a hundred years, we should then be consuming 160 million tons of coal a year for nitrogen fixation, or only ten per cent of the coal which is being used in the world to-day. At least two-thirds of the coal consumed in the fixation of nitrogen is used for power production, so we could reduce the coal required to one-third the value mentioned if other sources of power were available. There are still large areas of the world suitable for cultivation. It is therefore improbable that all the food requirements for the growing population of the world will have to be supplied exclusively from nitrogenous fertilisers for some time to come.

DISTRIBUTION OF NITROGEN FERTILISER.

Let us now investigate the use which the world makes of the nitrogenous fertilisers available at the present time. I have already mentioned that of the 1,843,000 tons of nitrogen consumed in 1928, 1,658,000 tons or 90 per cent was used in agriculture.

In Table III. are shown the quantities of nitrogen consumed in the different countries during the year 1928.

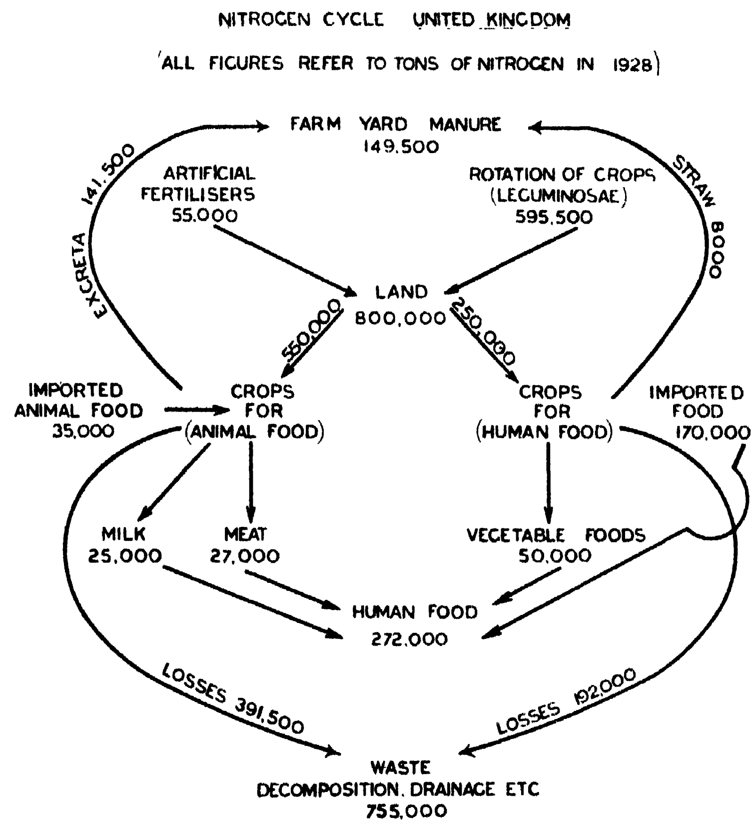

FIG. 2.

How much atmospheric nitrogen is combined by electric discharges? How much by bacteria? How much by our synthetic ammonia processes? How much humus changes to give nitrate? How much nitrate is washed away and how much goes into

TABLE III.

	Nitrogen Consumed.	
	Metric Tons, 1928.	Lb./Acre Arable.
Germany	615,200	22·3
France	166,900	6·7
Belgium	63,600	45·9
Czechoslovakia	33,800	5·0
Denmark	29,100	9·8
Holland	73,400	70·6
Italy	68,300	4·7
Poland	54,600	2·7
Spain	67,300	3·8
Great Britain	61,600	10·4
Total (Europe)	1,134,800	..
U.S.A.	383,600	2·4
Japan	113,300	16·8
Egypt	35,900	9·2
Other countries	175,600	..
Total (World)	1,843,200	..

the crop? What happens to that going into the crop and how much of it forms humus? What happens to the dissolved nitrogen going down the rivers into the sea? How much comes back to land in the form of fish? Again, how much nitrogen is liberated again from combination? Is there a dynamic equilibrium in this nitrogen cycle—or are we drifting in one direction? Are we gaining nitrogen in the air or are we losing it?

We cannot get answers to these questions. There is no doubt that, in the past, nitrogen was stored up in coal and in Chile nitrate, and this is being liberated now, but we do not know whether nitrogen is being stored up anywhere at the present time. In the diagram, Fig. 2, I have made an estimate of the principal movements in the nitrogen cycle of Great Britain for the year 1928.

The vegetable food-stuffs consumed by man are estimated to contain 50,000 tons of nitrogen. If these are grown with a nitrogen efficiency of 20 per cent, then 250,000 tons of nitrogen is required in the soil. Of this nitrogen it is assumed that 50,000 tons go into vegetable foods, 8000 tons into straw which forms farmyard manure, and the rest, 192,000 tons, are washed out of the ground by rain water and lost to the rivers and seas. It will be noticed that I have assumed that the wastage of nitrogen derived from humus is the same as the wastage of nitrogen from artificial fertilisers. I have no direct evidence for this—I have no evidence at all; but I cannot think of a more reasonable assumption. I have taken no account of the vegetable and animal life on the moors and mountains except so far as it provides human food. Probably I have neglected some other important factors, but I make no apology for offering this first attempt at a nitrogen flow sheet for Great Britain.

We are now getting much better statistics of agricultural production than formerly, and I believe that consideration of these statistics with other statistics now available has opened up new fields of study in agricultural economics. I have calculated the average amount of nitrogen obtained from an acre of crops in different countries. The figures in Table IV. are for the year 1928. They were obtained by calculating the weight of nitrogen in each crop for each country and then adding up the total amounts of nitrogen for each country. This weight of nitrogen is then divided by the area on which the crops grew and we get the weight of nitrogen in the crop in lb. per acre average over the whole country. By crop we mean the portion of the crop taken away for consumption by man or animals: for example, of wheat the grain, of potatoes the tubers, etc. The rest of the crop usually goes back to the land and is considered as part of the agricultural system of the country.

Since some crops give a larger yield of nitrogen, in the useful part of the crop, than others, the figures in the table are to some extent affected by the different crops and different proportions of each ... grown in the country. But so far as I can If we fe ... effect of the different crops grown is of milk a day, ...r importance, and as the production of ... the farmers' business, we are not far wrong in considering the first column as an index of the agricultural efficiency of that part of the country under crops. In the second column is given that part of the nitrogen in the crop which has been supplied by artificial fertilisers. It is assumed that on an average 25 per cent of the nitrogen supplied to the land as fertiliser is found in the useful portion of the crop. The third column is the difference between the other two columns and is the weight of nitrogen in the crop which has been supplied by the land. In countries with a good system of farming and a good rotation of crops this quantity is high. We see that the system of agriculture in Denmark produces more than twice as much as that in Canada, U.S.A., and Italy, and that in Great Britain we are a little better than Belgium and considerably better than Holland in our agricultural system, apart from the use of artificial nitrogen fertilisers. But since Holland uses seven times and Belgium four times as much nitrogen fertiliser per acre, these two countries obtain greater crops than those obtained in Great Britain, as is shown in the first column.

TABLE IV.

Year 1928.	Lb. per Acre.		
Country.	Total Nitrogen in Crops.	Nitrogen in Crops from Artificial Fertilisers.	Nitrogen in Crops from Humus.
Denmark	52·0	2·4	49·6
Holland	49·0	17·6	31·4
Belgium	47·2	11·5	35·7
Great Britain	40·2	2·6	37·6
Japan	34·2	4·2	30·0
Germany	32·5	5·6	26·9
Egypt	31·6	2·3	29·3
France	23·5	1·7	21·8
Canada	21·8	0·1	21·7
U.S.A.	20·8	0·6	20·2
Italy	20·5	1·2	19·3

In Holland one-third of the crops appear to be grown from nitrogen fertilisers. There seems to be no climatic or other physical reason why fertilisers should not be used to a greater extent in Great Britain. If we used as much per acre as in Holland, we should consume 420,000 tons of nitrogen per year; if as much as in Belgium, 272,000 tons; and if as much as in Germany, 132,000 tons. The reason that we do not use more fertilisers does not appear to be economic. The use of sulphate of ammonia yields 100-300 per cent on the money invested within a year. Consider the special case of the fertilisation of wheat. For some years the price of wheat and of sulphate of ammonia has been practically equal. Since 1 cwt. of sulphate of ammonia gives an increased yield of wheat of 2·4 cwt., even after paying for phosphatic and potash fertilisers, one hundred per cent will be earned on money spent on nitrogen.

Development of the nitrogen fixation industry has lowered the price of nitrogen fertilisers, so that we can expect the needs of the increasing population of the world to be met first by more intensive cultivation of land close to the markets for food rather than by extension of the cultivated area.

The Biological Method of Pest Control.

By Dr. A. D. IMMS, F.R.S.

PHYSICO-CHEMICAL methods of controlling noxious insects present the advantage that they generally check their activities sufficiently to enable the grower to produce a reasonably satisfactory crop. They are, however, at the best only palliatives the application of which entails an increase in costs of crop production. Furthermore, they usually need to be repeated year after year, because they fail to reduce a given pest population to a low enough level, in any one season, to prevent its subsequent recurrence or increase. For the most part, however, they are the best general control measures so far devised. Notwithstanding this fact, there are many insect pests that are not amenable to any method of artificial control. In attempting repression in such cases other means have to be sought, and a possible method often presents itself in the utilisation of the natural parasitic (and predaceous) enemies of specific pests. This procedure has come to be known as biological control, and it has produced the most encouraging results where pests have become accidentally introduced into lands they did not previously inhabit. Their natural enemies being left behind, such pests, unchecked by biological agents of this kind, quickly gain the ascendancy.

Biological control aims at restoring, so far as possible, the missing parasite factor. It has to be remembered that some of these introduced pests are numbered among the worst of the world's enemies of food supplies. Artificial control measures have, in many cases, proved impracticable and their application has involved vast expenditure of money to no real advantage. Biological control has consequently been resorted to as a sounder and, in the end, a less expensive measure. In a number of cases highly satisfactory results have been achieved, but the method is too immature to forecast its ultimate possibilities and its limitations with any certainty. Every year, however, brings fresh records of promising results, but it cannot be regarded as a universal panacea as the misinformed are too prone to view it.

The first essential for success is technical knowledge of the behaviour of specific parasites in relation to their hosts, from every point of view. Such knowledge forms the guiding principle in biological control work: it enables the most suitable parasites to be selected and the chances of failure or mistakes to be reduced. The collection of biological data of this kind is the work of highly trained entomologists, who must have the use of the equipment and technique pertaining to a subject which has its special requirements. They must also be field naturalists, capable of studying the ecology of parasites in different countries in relation to different conditions. A further necessity is experience in the transportation of delicate insects over many thousands of miles of land and sea, where drastic climatic changes may be encountered *en route*. At the destinations of these living cargoes fully trained specialists are likewise necessary. Familiarity with the handling, breeding, and liberation of parasites under favourable conditions can alone prevent loss of valuable material and wasted effort.

The more trade is fostered within the British Empire, the greater are the chances of the spread of pests from one land to another. The most efficient quarantine has so far failed to preclude this transfer taking place at one time or another. As already mentioned, it is largely against such introduced enemies that biological control offers promise of success. The basic food plants of Europe are grown in most of the Empire, and, consequently, parasites of the enemies of such plants have mainly to be sought out in Europe. These facts, taken in conjunction with the growing importance and demand for biological measures, have received timely recognition from the Empire Marketing Board. By providing financial aid it has enabled the Imperial Institute of Entomology to establish a special laboratory for the furtherance of the method at Farnham Royal, Bucks. A grant of £15,000 for capital expenditure led to the foundation, in 1927, of what is certainly the most adequate laboratory of its kind in the world. An annual maintenance grant for five years has led to its rapid development. That the creation of this laboratory has met a real need in Empire entomology is borne out by the number of requests for assistance that have already come in from various dominions and colonies. Its establishment renders the British Empire no longer so dependent upon the good-will of the United States for assistance in this direction. The Federal Government at Washington has fully realised the value of biological control and now expends more than £100,000 per annum on work of this character.

A general account of the aims and underlying principles of biological control has been recently published by the Empire Marketing Board in a *Bulletin*,* under the authorship of Dr. W. R. Thompson, the superintendent of the Farnham Royal Laboratory. In the same publication he gives a full and most interesting description of the organisation, facilities, and progress of the work of the Laboratory. During the brief existence of the latter more than 73 consignments of beneficial insects, containing over 285,000 living individuals, have been sent out to where demands came. These consignments represent about 24 species attacking about 17 different kinds of hosts. Also about 29,000 examples of Chrysomelid beetles have been shipped to Australia with the view of attempting to control St. John's wort by the aid of their phytophagous propensities.

This *Bulletin* is to be commended to all entomologists and to anyone interested in the practical applications of biology. In one respect it is unique,

* "The Biological Control of Insect and Plant Pests. A Report on the Organisation and Progress of the Work of the Farnham House Laboratory." Pp. 124+7 pl. E.M.B. 29. By Dr. W. R. Thompson. (London: His Majesty's Stationery Office, 1930.) 1s. net.

in that it explains the whole procedure of biological control and its underlying principles. It will obviously prove most helpful to have such information gathered together in so convenient and authoritative a form. There may be differences of opinion here and there on the theoretical side of the subject, but only one criticism of any importance need be raised. On page 25 an erroneous impression is conveyed with reference to the outstanding work of the Hawaiian entomologists and their methods. Probably in no part of the world has greater skill or care been exercised in biological control than in these Pacific Islands, and the successes achieved have been truly remarkable.

Radio Telephony at the Rugby Station.

PROGRESS is being made rapidly in the development of the Post Office radio transmitting station at Rugby. On the invitation of Sir Thomas Purves, Engineer-in-Chief to the Post Office, who is also president of the Institution of Electrical Engineers, many of the members of the Council of the Institution visited this station on Sept. 30 and were much impressed by the new developments.

In 1927, the first international telephone service designed for connexion with the ordinary telephone subscribers' system was started with one channel between the United States and England. There are now four channels and preparations are nearing completion for a fifth channel. Two of these channels use long waves and three short waves. The short wave systems are cheaper to erect, but they are not so trustworthy as the long waves. For the latter system, there are twelve masts, each 820 feet high, supporting the antennæ. The single side band telephone transmitter G.B.T. is the most powerful radio telephone transmitter in the world. Its wave-length is 5000 metres (60 kilocycles) and its output is equivalent to a broadcast transmitter of 1000 kilowatts. It is wonderful to notice how a current of several hundred amperes is apparently transmitted directly into the ether.

There are now a large number of smaller towers arranged in groups called 'arrays', the heights of which vary from 120 to 180 feet. These towers are used to support the antennæ for the short wave beam telephone services. The arrays are so arranged that the beam is projected in the direction of the great circle joining the transmitting to the receiving station. Three different frequencies are used, depending on the time of day the message is sent, and the message sometimes travels one way round this great circle and sometimes the other way.

The G.B.R. telegraph transmitter is the most powerful one in the world and works at 600 kilowatts and 16 kilocycles. The ninth harmonic of a tuning fork which oscillates at 1777·7 cycles is used to tune the circuit. In the final amplifier stages of G.B.R. each panel contains eighteen cooled anode valves.

By combining both short wave and long wave systems, the Post Office can now provide an effective service to America over the full twenty-four hours. It is not considered possible to operate long wave systems to greater distances than from England to North America. The solution of the problem of providing communication with the Dominions has been obtained by the use of short wave transmission.

In order to prevent unauthorised persons from 'listening in' to the private telephone messages which are now being sent almost continuously, a method has been devised of making the speech as transmitted quite incoherent to the would-be listener. The component parts of the speech are 'scrambled', that is, they are split up into portions by an electrical device and transmitted in this state, being finally rearranged in their correct form at the distant end. Demonstrations were given to the visitors, through the medium of a loud speaker, of the London side of conversations with New York through the long wave channel. The scrambled speech sounded absolutely meaningless. A somewhat different system of scrambling is adopted in the short wave system. In this case the frequencies of the various sounds are inverted, the high frequency sounds becoming low frequency and vice versa. The sounds produced by the waves in the intermediate stages remind one of barking dogs or crowing cocks.

The Rugby station is used for the ship and shore telephone service. The messages to the *Majestic*, the *Olympic*, the *Leviathan*, and other vessels, are sent out from here.

The electric power required to work the station is obtained from the system of the Leicestershire and Warwickshire Power Company by means of two underground cables, each capable of taking the full load of the station. The cables can be connected to either the Warwick or Hinckley power stations, so that the risk of a failure of the power supply is almost negligible. Short wave services to Australia, South Africa, Canada, India, and the Argentine are either complete or nearing completion. As the site covers 900 acres, there is plenty of room for extension.

Obituary.

PROF. W. D. MATTHEW, F.R.S.

PALÆONTOLOGISTS, zoologists, and geologists mourn the loss of Dr. William Diller Matthew, professor of palæontology in the University of California, who died on Sept. 24, aged fifty-nine years. For thirty years he shared the charge of the fossil vertebrates in the American Museum of Natural History, New York, and added greatly to the collection by his own discoveries in the western States. In 1927 he was appointed to the professorship at Berkeley, where he looked forward to extending the palæontological museum of the University of California by renewed activity in collecting fossils on the Pacific border of the American continent.

This important task, for which Prof. Matthew was so well fitted, has unfortunately been interrupted by his untimely death.

Matthew was born at St. John, New Brunswick, Canada, the son of Dr. G. F. Matthew, a well-known Canadian amateur geologist who added much to our knowledge of the oldest fossiliferous rocks of eastern Canada. He inherited the disposition for geological research from his father, and on leaving school proceeded to Columbia University, New York, where he eventually graduated as Ph.D. In the beginning, his inclinations were towards mineralogy and mining geology, and his first scientific paper dealt with topaz from Japan. For three or four years he spent his leisure in studying the crystalline and volcanic rocks of New Brunswick, and he published several valuable results. At the same time, he was an all-round naturalist, and his papers on some American species of the plant *Cuscuta* and on a trilobite *Triarthrus* show an early interest in the world of life. He attracted the notice of Prof. H. F. Osborn, who was then beginning to organise the great department of vertebrate palæontology in the American Museum of Natural History, and in 1897 he was selected as one of Prof. Osborn's assistants. Thus began his career as a distinguished student of extinct mammals and other higher vertebrates.

Matthew's first original research at the American Museum was a revision of the earliest remains of Tertiary mammals found in New Mexico, and his paper on the subject published in the Museum bulletin at the end of 1897 showed that these mammals belonged not to one but to two successive faunas, the Puerco and the Torrejon. It was the beginning of a long series of technical descriptions of the remains of Tertiary mammals which appeared in the Bulletin and Memoirs of the American Museum of Natural History, and is interesting as already displaying the keen insight into the bearing of the facts on wide problems which characterises all Matthew's writings. Cope had supposed that the bones of the two rows of the carpus and tarsus in the earliest Tertiary mammals were always directly opposite, and that interlocking began only in later groups. Matthew proved that such interlocking had already begun in the earliest Eocene.

As examples of his later publications may be specially mentioned those on the deer, early rodents, and cats. He showed that the deer must have evolved in the Old World, and that their succession in North America resulted from a series of immigrations. He described and discussed a group of Eocene rodents which may have been the primitive stock from which many later groups descended and diverged. He distinguished among the fossils from the Oligocene period onwards two parallel series of Felidæ, one ending in the existing true cats, the other in the sabre-toothed tigers which became extinct just before historic times. These and many other problems in the evolution of mammals Matthew discussed finally, with fullness of knowledge and experience, in a valuable paper entitled "The Evolution of the Mammals in the Eocene", in the *Proceedings* of the Zoological Society of London for 1927.

In a more general way Matthew was also interested in the extinct birds and reptiles. In 1917 he joined Mr. Walter Granger in a valuable description and discussion of the skeleton of a gigantic running bird, *Diatryma*, from the Eocene of Wyoming. With Mr. Barnum Brown he described Megalosaurian Dinosaurs from the Cretaceous of Alberta. He also described part of a skull of the only known horned Pelycosaurian from the Permian of Texas.

While occupied with this detailed research, Matthew meditated on many general questions which confront the geologist and palæontologist, and he summarised his ideas in two most suggestive publications. The first is entitled "Climate and Evolution", in the *Annals of the New York Academy of Sciences*, vol. 24, 1915. The second is a synopsis of lectures in palæontology in the University of California issued in 1928. Our knowledge of the evolution of the land vertebrates of past times is supposed to be scanty because those which inhabited the uplands and forests are scarcely ever represented among fossils. The early mammals are so imperfectly known because they lived in the forest regions of the north– Siberia, Canada, or Alaska—which have not yet been thoroughly explored. Dispersal and evolution are said to be due chiefly to geographical and climatic changes.

Matthew's scientific researches are recorded not only in his own publications, but also in other works of the American Museum, of which he was a most generous and unselfish helper. In later years he co-operated in interpreting the wonderful discoveries of fossil mammals in Mongolia, and in 1926 he himself visited China to further the research in progress there. Nor did he neglect the educational aspect of the Museum's activities. His handbooks on "The Evolution of the Horse", "Mammoths and Mastodons", and "Dinosaurs" are admirable examples of popular exposition.

Matthew's quiet, lovable personality, delightful sense of humour, and unassuming scholarship made him a welcome guest wherever he appeared in his many travels, and he had a multitude of friends. He retained his Canadian nationality to the end, and was elected a fellow of the Royal Society in 1919. A. S. W.

WE regret to announce the following deaths:

Mrs. Anna Botsford Comstock, emeritus professor of nature study at Cornell University, and wife of Prof. J. H. Comstock, emeritus professor of entomology in the same university, on Aug. 23, aged seventy-five years.

Rev. J. G. Hagen, *S.J.*, director of the Vatican Observatory for more than twenty years, on Sept. 5, aged eighty-three years.

Mr. E. M. Holmes, emeritus curator of the Pharmaceutical Society of Great Britain, an authority on materia medica and also on algæ, on Sept. 10, aged eighty-seven years.

Dr. E. Alberta Read, assistant chief of the microanalytical laboratory of the U.S. Bureau of Chemistry, Department of Agriculture, and distinguished for her work on histology, on Sept. 1.

No disaster of post-War years has so deeply touched the minds and hearts of English-speaking peoples as that which overtook the airship *R101* near Beauvais early last Sunday morning. The airship, considered by those responsible for its design, construction, and navigation, as well as by those men of science who have laboured for years to make lighter-than-air vessels proof against the vagaries of the elements which they have to encounter, as the embodiment of safety, within a few hours of its release from its mooring mast at Cardington was reduced to a blackened framework of metal, and most of its crew and all its passengers, including Lord Thomson, Secretary of State for Air; Sir Sefton Brancker, Director of Civil Aviation; the brilliant and intrepid Major G. H. Scott, and Col. V. C. Richmond, responsible for the design of the airship; Mr. M. A. Giblett, of the Meteorological Office, and a familiar figure at British Association meetings, each of whom in his respective sphere was an inspiration to his fellows, have perished with the vessel which was to carry them to Egypt and India in triumph. The vessel itself could have been replaced. The loss of these splendid lives is more than a national calamity: it makes the world poorer. The loss of the airship by itself would, while they lived, have merely spurred them to greater efforts to justify their faith in the future of this type of craft. But it will occasion no surprise if the country as a whole, with this culminating disaster in mind and deprived of the enthusiasm and driving force of these pioneers, will find adequate reasons for refusing to go forward with schemes for further airship construction while the risk to valuable lives is manifestly so great.

Sir Richard Glazebrook, chairman of the Aeronautical Research Committee, in a letter to the *Times* of Oct. 7, pays grateful tribute to the scientific influence and service of several of the men whose loss the nation now deplores. Lord Thomson, he says, has ever been most helpful in the work of the Research Committee: Sir Sefton Brancker's enthusiasm was most infectious, and his interest in problems bearing on civil aviation most stimulating. Col. Richmond was a member of Sir Richard's staff in the Aeronautical Department of the Imperial College some ten years ago, and he was a leading authority on airship construction. Major Scott knew all there was to know about airship navigation, and his experience would have been of great value in the development of airship traffic in the future. Squadron-Leaders Bishop and Rope had both done notable work. During the War, when the rapid gauging of munition parts was of vital importance, Bishop invented improvements in the method which secured greater accuracy and greater speed. Rope is the author of a well-known article on airship lift in the "Dictionary of Applied Physics". Mr. Giblett had devoted himself for some years to meteorological problems bearing on airships, and our knowledge of the motion of the air in gusts and the distribution of 'gustiness' in a wind is largely due to his researches at Cardington. "All these men", adds Sir Richard, "realised in a marked degree that the development of the airship depended on the combination of scientific ability and the experience gained in flight. They gave of their experience freely; they utilised, wisely and wholeheartedly, all we could give them from our stores of mathematical learning and scientific knowledge. And now they are gone; their work will live, and my Committee would wish me, I know, to express their sense of its greatness, their sorrow for our loss."

It is interesting to compare the speeches made by the Prime Minister and other representatives of the British Commonwealth of Nations at the opening session of this Imperial Conference with those made at the corresponding session in 1926. In 1926, the dominant personalities at the Conference were Mr. Baldwin and Mr. Amery, representing Great Britain, and Mr. Bruce, the Prime Minister of Australia, all of whom believe that preferential tariffs are essential for the realisation of Imperial economic unity and prosperity. Nevertheless, the subject of tariffs occupied little of the time of the Conference, other forms of Imperial preference receiving far more consideration, particularly the means by which the various countries of the Empire could most effectively apply their scientific workers and reserves of scientific knowledge to the tasks of developing the vast potential resources of the Empire and combating the diseases afflicting or threatening its peoples, domestic stock, and plant products. As proof of the earnestness of Great Britain in the matter, Mr. Baldwin was able to point to the creation of an Empire Marketing Board with ample funds at its disposal for the furtherance of schemes for marketing Empire products and for the prosecution of research. This approach to the problems confronting the Conference was sufficiently novel and promising to awaken the keen interest of most of the Dominion statesmen present, and encouraged the hope that at future conferences even more time would be given to the consideration of the impacts of science on Imperial affairs.

It is disappointing to find so little indication in the opening speeches that the principal representatives at the present Imperial Conference appreciate the significance of these impacts on our material progress or realise their potentialities as an Imperial consolidating force. Neither Mr. MacDonald nor any of the other Prime Ministers found it necessary to refer to the fact that science has hitherto been applied almost exclusively to solving the urgent and vital problem of production, and that now the governments of the Empire—indeed, all governments—are confronted with a new one, namely, that of re-equipping the machinery of State and reorganising the system of finance so that the peoples of the world can take full advantage of their immensely increased productive capacity, which they owe to the application of science in the production of foodstuffs, essential raw materials, and manufactured goods. It is surprising that Mr. MacDonald did not take advantage of the exceptional opportunity offered him as chairman of this Imperial Conference to open its proceedings with a

survey of the work already done to further Imperial co-operation in various fields. To this he might have added an invitation to the Dominions to co-operate more fully with Great Britain in the task of developing the non-self-governing dependencies of the Crown, a field of work which could provide a magnificent outlet for the energies and initiative of the products of the universities of the Dominions.

FURTHER, Mr. MacDonald might have expressed an opinion on the fruitful suggestion conveyed to him some months ago in a memorandum drawn up by Sir Basil Blackett as the outcome of a series of discussions on Imperial economic co-operation by an authoritative group of politicians, men of science, and financial experts, that an Imperial Economic Body, deriving its authority and its income from the governments of the Empire, should be set up by the Imperial Conference. This body, it was suggested, should have a permanent secretariat similar to that of the Secretariat of the League of Nations, its functions being to deliberate and advise upon all questions affecting the economic and social well-being of the Empire, and to promote efficiency in production and marketing (*a*) by the development of a common service of economic intelligence and investigation and (*b*) by the promotion of co-operation in the application and dissemination of the results of scientific research. This, of course, would involve the new body in the assumption of responsibility for the work of the four existing inter-Imperial bodies, namely, the Imperial Economic Committee (including the Empire Marketing Board), the Imperial Shipping Committee, and the Mechanical Transport Council. The suggestion that there should be such an Imperial Economic Secretariat also has the support of the Empire Economic Union, the research committee of which recently published an illuminating report on the trade relationships and economic position of the various countries of the Empire. Such a permanent secretariat is badly needed. With this continuously working for the furtherance of the ideal of Imperial economic co-operation, and regular yearly meetings of an Imperial Council at which the countries of the Empire were represented, there would be some hope of continuity of policy between successive Imperial conferences.

DR. A. W. HILL, Director of the Royal Botanic Gardens, Kew, in his thoughtful and interesting inaugural sessional address to the students of the School of Pharmacy, delivered on Oct. 1, dealt first with the Doctrine of Signatures which was so widely accepted by herbalists and physicians during the Middle Ages, a doctrine which, while containing much that was fantastic, contributed very materially to the study of plants and the recognition of their medicinal value. According to this ingenious doctrine, every plant bore on some part of it, leaf, stem, seed, etc., some sign or indication of the part of the body diseases of which it would cure, or in its juice a resemblance to one of the four humours, namely, blood, yellow bile, black bile, or phlegm, disorders that it would alleviate: thus the lungwort (*Pulmonaria*), spotted with tubercular scars, was a specific for consumption; the blood-root (*Tormentilla*), which derives its name from the red colour of its roots, was adopted as a cure for the bloody flux; while the bryony, the root of which resembles the foot of a dropsical man, was a remedy for dropsy. Even the great naturalist, John Ray, believed that by the wise dispensation of Providence such species of plants are produced in every country as are good for the diseases prevalent in that country.

DR. HILL wisely recommended the study of the work of early pioneers in botany and medicine, remarking that "we are too apt to think that there is little to be found out by delving into the literature of the past . . . but it is somewhat surprising to find how much the early investigators, herbalists, monks, and others knew of the properties and uses of plants and how much we can learn from their writings". One might add to these very true remarks that much valuable information would doubtless follow from inquiries into the reasons why herbs that had a reputation when the herbs themselves were used lost that reputation when modern preparations were employed. Dr. Hill then proceeded to deal with the importance of studying the physiological varieties of plants and ascertaining in what respects these varieties, though at present botanically indistinguishable, differ in their chemical constituents. The example selected by Dr. Hill was that of *Eucalyptus dives*, the volatile oils of four physiological varieties of which differ enormously in the proportion of piperitone, cineol, and phellandrene which they contain. Mr. Penfold, in remarks quoted by Dr. Hill, says: "I am unacquainted with any evidence which shows the medicinal value of Eucalyptus oils to be due to cineol". "It is only", said Dr. Hill, "by the exercise of the observant faculties and by making deductions therefrom that we are able to make any real contribution to knowledge."

THE Eighth International Congress of the History of Medicine, to which we directed attention in our issue of Aug. 23, p. 292, was held in the Accademia dei Lincei at Rome on Sept. 22-28, under the presidency of Dr. Pietro Capparoni, professor of the history of medicine at Pisa, with Prof. Castiglioni, who occupies the corresponding chair at Padua, and Prof. Bilancioni, of Rome, as vice-presidents. About 230 members were present, from sixteen different countries. The British delegate was Dr. J. D. Rolleston, who also represented the Royal College of Physicians and the Royal Society of Medicine; the Royal College of Surgeons and the University of London were represented by Prof. G. E. Gask; the Society of Apothecaries by Dr. Vincent Dickinson; the University of Manchester by Dr. R. Whitehead; and the Wellcome Medical Historical Museum by Capt. P. J. Johnston-Saint. The most notable figures in the Congress were Prof. Karl Sudhoff, of Leipzig, the doyen of medical historians, and Prof. Georg Sticker, of Würzburg, the leading living writer on the history of epidemiology, who both took an active part in the proceedings.

IN addition to the papers referred to in our previous reference to the International Congress of the History

of Medicine, mention may be made of the following communications: the relations between the Accademia di Cimento and the Royal Society, by Dr. Mosè di Segni; malaria in contemporary poetry from Virgil to Carducci, by Signora Anna Celli, the widow of the eminent malariologist; madder in the history of medicine, by Dr. G. R. Cameron; and the appearance of chlorosis in the sixteenth century, by Dr. Axel Hansen. The receptions included an audience and address by the Pope in the Vatican; visits to the Bibliotheca Casanatense and Bibliotheca Lancisiana, where there was an exhibition of manuscripts, incunabula, and other rare medical works; excursions to Lake Nemi and inspection of Caligula's galley, as well as to Monte Cassino, where a bronze was offered to the monastery in recognition of its services to medical science in the Middle Ages. On his way to and from the meetings, as well as on the rare occasions when he was unable to escape the temptation to play truant, the student of social hygiene could not fail to be impressed by the conspicuous absence of beggars, prostitutes, and drink advertisements in the streets of Rome, which in this respect set an excellent example to those of London, Paris, and other large towns. The next Congress will be held at Bucharest in 1932.

SCOTLAND is soon to possess a Scottish National Trust, which will play in the northern kingdom a part similar to that of the original National Trust, the activities of which are in practice confined to England and Wales; that is to say, it will constitute a body of trustees, governed by a council, to which benefactors may convey lands and properties, and which may from time to time take steps to secure properties in the national interest as funds permit. The Trust will be a registered company, limited by guarantee, with a council or board of control and such other administrative apparatus as its subsequent development may make necessary. Private individuals up to any number may become members of the Trust on payment of an annual subscription of one guinea, to which amount personal liability will be limited. The Trust is to be promoted by the Council of the Association for the Preservation of Rural Scotland, and a provisional council, of which the Duke of Atholl has accepted the presidency, has been formed. The move is a laudable one, but in view of the fact that a Government Committee has been investigating with thoroughness the possibilities of setting aside areas in Great Britain for the people, no harm would have been done had the promoters had the patience to wait for and perhaps benefit by the recommendations and suggestions of that Committee.

DURING the coming winter a course of lectures on "Native Races of the Empire" will be given under the auspices of the Royal Anthropological Institute. The lectures will be popular in character, following in this respect the course given last year on "Early Man". Each lecture will deal with the people of a single area. In addition to giving a general account of the people, the lectures will illustrate the bearing of the study of their culture on the problems of the administration of their affairs under European jurisdiction. The first lecture of the series will be given by Prof. J. L. Myres, president of the Royal Anthropological Institute, on Oct. 15, at 5.30 P.M. He will deal, among other matters, with the general aspect of the relation of anthropological studies to administration, under the title of "Native Races of the Empire: Facts and Problems". The second lecture will be given on Nov. 12, by Mr. A. M. Hocart, on "Spirit Worshippers of the South Seas"; and on Dec. 10, Lord Raglan will lecture on "The Tribes of the Anglo-Egyptian Sudan". Further lectures in the series will be given after Christmas on Jan. 15, Feb. 10, and Mar. 10. Subjects and speakers will be announced later. The lectures will be given in the Portland Hall of the Regent Street Polytechnic Extension, Little Titchfield Street, Great Portland Street, W. Admission will be free.

THE expedition by submarine across the Arctic Sea suggested some time ago by Sir Hubert Wilkins is now taking definite shape. Science Service, of Washington, D.C., announces that an American submarine, withdrawn from the United States navy, has been acquired and named *Nautilus*. It is a small vessel with a submerged displacement of 566 tons. The cruising radius on the surface is 3000 miles, or with emergency fuel, 5500 miles. It is believed that the vessel, stripped of its fighting equipment, will be able to travel at least 175 miles submerged. Lieut.-Commander S. Danenhower will be in command of the *Nautilus*, and Dr. H. U. Sverdrup, who served six years with the Norwegian *Maud* expedition, will be in charge of the scientific work. The course proposed is from Alaska to Spitsbergen. Dr. Sverdrup believes that during July and August the pack will prove to be so open that the submarine will be able to come to the surface every five miles if necessary. On the other hand, it is hoped that the ship will prove capable of breaking through young ice, the position of which can be ascertained by the intensity of the light under water. Some soundings are to be made throughout the voyage, as well as gravity and magnetic observations. Physical observations on the sea water will be taken at different depths.

THE presidential address of Mr. J. G. Lawn on "Periodical Variations in the Prices of Minerals and Metals" delivered in June to the Institution of Mining and Metallurgy, appears in the July issue of the Institution's *Bulletin*. Variations of prices of minerals is a subject which the professional mining engineer frequently overlooks, as to a large extent it lies outside his normal terms of reference. The price of working a mine must be more than balanced by the price received for its products. Fluctuations in working costs can be more or less allowed for by individual operators, and the mining engineer's experience comes into play very largely either in the budget for such allowance or in devising methods of keeping the figures below an economic danger-mark. But prices of products may be governed by national or international circumstances: they soar or are depressed according to conditions, political and otherwise, over which the average

single company has but little control. Thus, beyond an occasional glance at current figures, usually confined to the metals in which he is specially interested, the professional man gives scant attention to the matter.' Mr. Lawn dealt with his subject ably under three heads, the metals as money, the relative prices of metals, and periodical variations in prices of minerals and metals. He showed clearly that knowledge of this economic question is very much the concern of the mining engineer, as its obvious influence on operations at the mines themselves is to-day forced home in practically every undertaking. It is as well in these days of severe industrial depression that we are brought to realise that even an honourable profession may become a fool's paradise if the plain ' bread and butter ' facts of life remain long disregarded.

IN the August issue of the *Aeronautical Journal* appears the full report of a lecture given by Dr. J. W. Maccoll on modern aerodynamics research in Germany. The paper is valuable in that it gives a very comprehensive account of the intensive research in aerodynamics that has been conducted in Germany—especially on the problem of turbulence—during the past few years under the inspiration of Prandtl and Kármán. The earlier parts of the paper treat of the boundary layer theory and its application to laminar and turbulent motion, the experimental and theoretical investigations into the origin of these states, and the analysis of the characteristics and inner mechanism of fully developed turbulence. Workers in the subject will find this paper of great value because of the systematic arrangement and exposition of the enormous amount of work in this field that has been conducted in Germany. Incidentally, the essential empiricism of the present German school is very apparent in the nature of the assumptions that are made at each stage where the mathematical difficulties appear too severe.

THE tenth Annual Report of the Non-Ferrous Metals Research Association and the July number of the *Bulletin* of the Association have recently been issued. We have already referred to the finances of the Association and to the new headquarters, where much of the work will in future be concentrated. The experiments on ternary alloys of lead, which have brought about a marked improvement in cable sheathings for positions subject to vibration, such as on railways, have led to further developments in the making of water pipes and lead roofing. Another product of the research work of the Association is the aluminium brass for condenser tubes, and this material is now undergoing tests on a large scale in practice. The Report contains particulars of many other investigations, some of which have been conducted in central laboratories and others in university and other institutions in close touch with the Association. This policy of co-operation has proved to be of great value in the training of research workers, in addition to its immediate results. The information service, which is on an extensive scale, has already served as a model to other organisations, and such reports as that just issued supply adequate proof of the usefulness of the system of research associations under the scheme of the Department of Scientific and Industrial Research, provided that a competent staff can be secured, as in the present instance.

THE growing number of international organisations, more especially in the electrical field, has led the Institution of Electrical Engineers to appoint an International Relations Committee to discuss the question of the best way to co-ordinate British participation in them. The International Electrotechnical Commission (I.E.C.) is the oldest of these bodies and has done admirable work in its somewhat limited field, its specific purpose being to obtain agreement on standardisation questions. At the recent technical sessions of the I.E.C. held at Stockholm, an informal preliminary discussion on this subject was opened by Mr. P. Good, an English delegate. In comparing the other international bodies with the I.E.C., he pointed out that their primary purpose was the exchange of information and experience and the bringing in personal contact of those engaged in similar work in different countries. Recent experiences have shown that congresses of this kind have already reached the stage of being overburdened with papers which receive little attention, and some of them are not up to the standard of, or suitable for, international discussion. There is great need for co-ordination in the international field in order to avoid overlapping of effort. Mr. Good suggested the possibility of changes being made in some of the existing organisations or the merging together of them into a body which should be representative of the electrotechnical industry as a whole throughout the world. It would have the funds to promote continual international exchange of technical information and when necessary it could call conferences. An organisation of this nature would have to be governed by properly formed national committees, each of which would have the responsibility of seeing that the papers contributed by its members were of a standard which justified international consideration.

THE problem of measuring the temperature of the air is much more difficult than would be supposed by anyone who has not attempted it, because of the necessity for eliminating the influence of radiation, which affects the thermometer very readily but the air only in an indirect way. If any kind of self-registering thermometer is to be used, the Stevenson screen has long been the standard method in Great Britain. In that screen a reasonably free circulation of air is secured by the use of louvres, and direct radiation is at the same time prevented from reaching the thermometers; much stress is always laid on the importance of having the screen painted white. In a paper by Barkat Ali (Scientific Note No. 11 of vol. 2 of the "Scientific Notes" of the Indian Meteorological Department) the results of comparative observations made with three teakwood Stevenson screens, painted black, painted white, and unpainted, are summarised. The observations were made at Agra between May 15, 1925, and Feb. 28, 1926, that is to say, during a period including many days with solar radiation of an intensity never

experienced in the British Isles. The results were surprising. In place of the large differences that might have been expected during the daytime between the black and the white screens, even the mean maximum obtained in them differed only by 0·8° F. By grouping the observations to include only the days of little or no cloud and wind the difference was increased only to 1½°F.; the mean of the maximum and minimum was practically identical for all three screens. The observations appear to imply that in the British Isles white paint is almost unnecessary, but since the wood needs protection against the weather and white paint is not expensive, it is obviously preferable to use it, even though a substance like linseed oil might be more lasting and even cheaper; readings made in dark-tinted screens can, however, be accepted as reasonably accurate where figures from a whitened screen are not available, the more so as there are various other more important sources of error in a large proportion of the climatological statistics accumulated by private and official observers in Great Britain.

THE *Eugenics Review* (vol. 22, No. 2) contains a biographical sketch of Mr. Henry Twitchin, a wealthy benefactor of the Eugenics Society, who died on Mar. 19 last, by Major Leonard Darwin. Mr. Twitchin had given the Society £1000 a year for some years, but his bequest will probably have an annual value of more than £3000. He was born in Berkshire from farmer ancestors, and after a training in agriculture he emigrated to Western Australia as a young man and took up sheep-farming. In 1924 he sold his estates, comprising more than a million acres of pastoral leases, and, after thirty-four years in Australia, returned to England. His interest in sheep-breeding early led him to recognise the importance of the principles of heredity as applied to man. Mr. Twitchin was for many years in correspondence with Major Darwin on the subject of eugenics, and his views are summarised in extracts from some of his letters. From 1912 until the day of his death he showed increasing interest in the aims and work of the Eugenics Society.

IT is announced by Science Service of Washington, D.C., that the National Academy of Sciences has accepted a trust fund of £5000 presented by a group of officials of the American Telephone and Telegraph Company in honour of General John J. Carty, vice-president of the Company, who recently retired from active connexion with the scientific research of that body. The John J. Carty Medal and Award for the Advancement of Science which will be supported by this fund may be "either for specific accomplishment in some field of science or for general service in the advancement of fundamental and applied science". It is to be awarded without regard to race, nationality, or creed. The award has been established as a testimonial to General Carty's "noteworthy contributions to the advancement of fundamental and applied science and in appreciation of his great service for many years in developing the art of electrical communication". General Carty is a past president of the American Institute of Electrical Engineers and is well known for his interest in transcontinental and transoceanic telephony.

REFERRING to his obituary notice of Prof. H. W. Wiley, which appeared in NATURE of Sept. 20, Prof. Henry E. Armstrong writes to inform us that his visit to America, when he first met Wiley, was in the summer of 1897, not in 1903.

A COURSE of lectures on "Contraception and Allied Questions"—the first course on this subject to be given in Great Britain - is being delivered in the lecture hall of the Royal Institute of Public Health, 37 Russell Square, London, W.C.1. The first lecture, on Oct. 9, is by Rev. Dr. A. H. Gray, on "Christian Civilisation and Contraception." The subjects dealt with in the course are of special importance at the present time, particularly in view of the memorandum recently prepared by the Ministry of Health for the guidance of local authorities, and also the fact that the medical schools in Great Britain do not provide courses of instruction on the subjects. The course has been specially planned to meet the needs of medical practitioners and senior medical students, and their admission to the lectures is free.

THE following appointments have been made recently by the Secretary of State for the Colonies: *Colonial Agricultural Services*: Mr. C. A. Thorold, to be assistant mycologist, Kenya; Mr. V. Dawson, to be assistant agricultural instructor, Federated Malay States; Mr. H. D. Leighton, to be agricultural field officer, Federated Malay States; Mr. B. A. Lowe, to be assistant botanist, Federated Malay States; Mr. J. P. Maule, Mr. S. D. Ross, and Mr. J. West, to be superintendents of agriculture, Nigeria; Mr. J. R. Curry and Mr. N. R. Fuggles, to be district agricultural officers, Tanganyika Territory; Mr. H. M. Lloyd, to be entomologist, Tsetse Research, Tanganyika Territory; Mr. H. L. G. Milne, to be agricultural officer, Uganda. *Geological Survey*: Major N. R. Junner, director of Geological Survey, Sierra Leone, to be director of Geological Survey, Gold Coast. *Colonial Forest Services*: Mr. R. C. Barnard, to be assistant conservator of forests, Federated Malay States; Mr. T. F. Betts and Mr. J. H. Mackay, to be assistant conservators of forests, Nigeria; Mr. W. J. Eggeling, to be assistant conservator of forests, Uganda.

THE Board of Control has issued a *Circular* (No. 745) and *Memorandum* on the Mental Treatment Act, 1930, reviewing the provisions of this Act, which comes into operation on Jan. 1, 1931. The Act provides for various alterations in administration and embodies the following principles: (1) The preventive treatment of incipient mental illness by the provision of out-patient clinics and extended facilities for voluntary treatment. (2) A further advance in assimilating the treatment of mental illness to that of other forms of illness, (*a*) by provisions under which certain cases may be temporarily placed under care and treatment without 'certification', and (*b*) by the opportunities afforded of associating the general hospitals (municipal and voluntary) in the treatment of mental illness. (3) Extended provision for after-care and for systematised research into mental illness. (4) Dissociation of the treatment of mental illness from

the poor law. (5) Various important alterations in terminology reflecting the more enlightened view now taken in regard to mental illness.

THE publication of "A Survey of Scottish Coking and Furnace Coals" (Physical and Chemical Survey of National Coal Resources, Paper No. 15. London: H.M.S.O., 4s. net), by T. Gray, T. H. P. Heriot, and W. J. S. Killing, is a reminder of the sort of difficulties, all too common during the War, which might have been avoided by the more scientific study of national raw materials. In 1916, when the need for increasing the supply of steel became urgent, it was found necessary to investigate the supplies of coking and splint coals available in Scotland for the manufacture of pig iron. Prof. T. Gray, of the Royal Technical College, Glasgow, undertook the responsibility for this survey, which has now been published in response to numerous requests. It contains reports on 367 samples from all the Scottish coalfields, and records the suggestion for improving the coke from such coals by increased rate of carbonisation, now generally adopted, by the use of higher temperatures and narrower ovens.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A senior engineering assistant (Grade G) and an engineering assistant (Grade F) in the Borough Engineer's Department, County Borough of West Ham—The Borough Engineer, Town Hall, West Ham, E.15 (Oct. 20). Two veterinary surgeons, one with bacteriological and pathological knowledge and experience of laboratory technique, and one for meat inspection work, under the New Zealand Government—The High Commissioner for New Zealand, 415 Strand, W.C.2 (Oct. 21). A part-time radiologist at the Selly Oak Hospital—The Medical Superintendent, Selly Oak Hospital, Birmingham (Oct. 22). An assistant radiologist at the Dreadnought Hospital, Greenwich—The Secretary, Dreadnought Hospital, Greenwich, S.E. (Oct. 27). A deputy director of the laboratories of the Public Health Department, Cairo, and a first bacteriologist in the laboratories of the Public Health Department, Cairo—The Under-Secretary of State, Department of Public Health, Cairo (Oct. 30). A geneticist in the Agricultural Department of Jamaica for work, partly, on the breeding of bananas immune from the Panama disease—The Private Secretary (Appointments), Colonial Office, 2 Richmond Terrace, Whitehall, S.W.1 (Oct. 31). A John Harling fellow in physics in the University of Manchester—The Registrar, The University, Manchester (Nov. 1). A lecturer in civil engineering at Armstrong College—The Registrar, Armstrong College, Newcastle-upon-Tyne (Nov. 1). Assistant surveyors in the Admiralty and in the Air Ministry—The Secretary, Civil Service Commission, Burlington Gardens, W.1 (Jan. 22). A director of the Natal Museum—The Secretary to the Board of Trustees, Natal Museum, Pietermaritzburg, South Africa (Jan. 31). An assistant in the Pathological Laboratory of the Cancer Research Department, Bristol Royal Infirmary—The Secretary and House Governor, Royal Infirmary, Bristol.

Our Astronomical Column.

New Comet or Asteroid?—U.A.I. Circ. No. 299 announces that M. E. Delporte has detected an interesting object (either planet or comet) on a plate taken at Uccle Observatory in the following position:

U.T. 1930.	R.A., 1925·0.	S. Decl. 1925·0.	Mag.
Sept. $29^d\ 0^h\ 7^m\ 6^s$	$23^h\ 41{\cdot}8^m$	$2°\ 30{\cdot}4'$	12·0

The daily motion is $-1^m\ 43^s$, N. 11′ 56″. This is unusually large for a minor planet, so if the object is a planet it has probably an interesting orbit not very far outside that of the earth. The object is well placed for observation, being not far from opposition.

Occultations at the Union Observatory, Johannesburg.—In recent years there has been a remarkable awakening to the value of occultations of stars by the moon for finding the errors of the lunar tables. One great advantage is that the points on the moon's limb are much more widely distributed than in the case of meridian observations; in the latter an elevated or depressed region on the limb may affect observations systematically. Dr. Innes was one of the first to inspire the new campaign, and the work has been energetically carried on at Johannesburg since his retirement. *Circ.* No. 32 of the Observatory (May 19, 1930) contains the observations and reductions (by W. M. Worssell) of 152 occultations observed in 1929; of these, 126 were observed between new and full moon, the remainder after full. The method of reduction suggested by Prof. Brown was to apply a constant mean correction to the moon's mean longitude, this being determined each year by the results of preceding years; the smallness of the residuals after applying this correction gives striking evidence of the excellence both of the observations and of Brown's lunar tables, once the mean error has been taken out. At Johannesburg, Brown's method is varied slightly; instead of applying a constant to the moon's mean longitude, one is applied to the times used for interpolating the moon's co-ordinates. Thus 12·7 sec. was added to the times for the first half of 1929 and 10·9 sec. for the second half. This has the advantage of correcting all three co-ordinates, longitude, latitude, and parallax, by a single operation.

Observations of Meteors in Japan.—*Bulletins* No. 173 and 174 of the Kwasan Observatory, Kyoto, announce that numerous meteors, presumably associated with comet 1930*d* (Schwassmann-Wachmann) were observed, chiefly by Mr. Nakamura, on ten nights extending from May 24 to June 19. The radiant moved during this period from R.A. $15^h\ 19^m$, N. Decl. 43° to R.A. $16^h\ 19^m$, N. Decl. 39°. Parabolic orbits were deduced for the meteors; the node varied with the longitude of the earth, but the inclination was nearly constant, about 27°, the argument of perihelion about 201°, and the perihelion distance close to unity. The cometary perihelion was a few millions of miles outside the earth's orbit, so the meteors are considerably scattered.

The same *Bulletins* announce that Prof. Issei Yamamoto is preparing a general catalogue of comets, which he hopes to publish next year. It will contain all comets for which orbits have been computed, and notes upon those for which the data are insufficient to deduce orbits.

Research Items.

The Pyramids.—In *Ancient Egypt* for June, Sir Flinders Petrie discusses the constructional difficulties in building the pyramids and offers some suggestions as to the means adopted by the ancient Egyptians in overcoming them. Their construction involved earth banking on an enormous scale and the employment of levies of thousands of men moving quickly by main force. The lever and roller were practically the only appliances used. The Great Pyramid shows no trace of enlargement and the passage system demands almost the full size from the first. The earth ramp needed for its construction must have been of great size, almost of the volume of the pyramid itself; otherwise the final slope would have been too steep, while a full front was necessary to get up the 50,000 blocks required for each of the lower courses; also, to maintain the sides of an earth bank to the height of 400 feet would entail a base as wide. The bank was heightened as the work proceeded by waves of stone-work and earth-work alternatively moving up the bank. The height of the ramp is a difficult question. It cannot have been carried to the full height of the pyramid. Probably earth bank and brick facing rose to not more than 300 feet. At this level the face would be 150 feet wide. Above this the raising must have depended on a support of stone in the form of a stone ramp with a platform zig-zagging up the side. A platform and ramp of 20 feet each would suffice for getting up the stone for the upper courses. It would scarcely be practicable to carry a regular ramp higher than 12 feet below the capstone. The last six or eight courses would be raised by direct levering in a safety pit. Lastly, the capstone itself would be levered up on stone blocking outside the completed faces, on a sort of pedestal of blocks, until it reached its proper level. From a platform thus outside the pyramid face it would be slid forward on rollers until finally in place. The staging of stone would then be taken off and the top courses trimmed down to the slope, about four feet at a time.

Pedigrees of Hereditary Disease.—In a paper entitled "Some Pedigrees of Hereditary Disease" (*Annals of Eugenics*, April 1930), Dr. Julia Bell makes a contribution to the records of polydactylism and syndactylism, and the association of blue sclerotics with fragility of bone. Among eight families the pedigrees show the transmission of the former defects through several generations. The data are not considered sufficient to permit any conclusion being drawn as to the sex incidence, but it is clear that such digital anomalies varied greatly in the intensity and mode of their inheritance, while a considerable number of cases investigated yielded no evidence of any familial incidence. Dr. Bell refers to the fact that while the association of polydactylism with retinitis pigmentosa and hypopituitarism is rare, this syndrome is found in all affected members of the family when the association does occur, and that the parents have no reason to suspect the existence in themselves of any hereditary taint. In the case of blue sclerotics, Dr. Bell points out that the highest incidence is to be found in females, which is an uncommon observation in the transmission of hereditary defects. The thin condition of the sclerotic which is the actual cause of the characteristic colour may occur without any associated anomaly of bone, but if fragilitas ossium is exhibited by any member of a family, that individual will invariably show the accompanying anomaly in the eye.

Salt-loving Beetles of the North.—Dr. Hans v. Lengerken has described the maritime and sub-maritime beetles of the shores of the North Sea and Baltic ("Die Tierwelt der Nord- und Ostsee". Begrundet von G. Grimpe und E. Wagler. Lieferung xvi. Teil xi.el: "Halophile und Halobionte Coleoptera". Leipzig: Akademische Verlagsgesellschaft m.b.H., 1929). His large work recently published, "Die Salzkäfer der Nord- und Ostseeküste", shows Dr. Lengerken to be the principal authority on the subject and chiefly owing to his work the beetles of these coasts are thoroughly known. A surprising number love the salty districts, and, although not usually actually living in the sea, for the whole of their life they may be, and in many cases must be, in the proximity of salt water. Only one truly marine species is to be found in these regions, and this is *Haemonia* (*Macroplea*) *mutica* F. (Chrysomel.); the remainder live on the coasts and are either dependent on the presence of salt water in the near neighbourhood, 'halobionte', or live both in salty and un-salty districts, 'halophile'. Taking both together, there are 111 species recorded from the shores of the North Sea and Baltic. Most of these are predatory in their habits. After a short introduction, a table of distribution is given and the systematic portion follows in which the genera are diagnosed and the species recorded, with notes on their habitat and sometimes on their habits and life-histories. There are only nine figures in all, which is to be regretted, as those given are very good.

Fishes from the *Albatross* Expedition.—Mr. Henry W. Fowler and Mr. Barton A. Bean have finished a third instalment of the report on the fishes collected by the United States Bureau of Fisheries steamer *Albatross* entitled "The Fishes of the Families Amiidæ, Chaudidæ, Dulcidæ, and Serranidæ, obtained by the United States Bureau of Fisheries Steamer *Albatross* in 1907 to 1910, chiefly in the Philippine Islands and Adjacent Seas" (Contributions to the Biology of the Philippine Archipelago and adjacent regions. Smithsonian Institution. *U.S. National Mus. Bull.* 100, Vol. 10. 1930). This is the first report on the percoid fishes, limited to the more typical perchlike families, particularly the Amiidæ and Serranidæ, which are much the most numerous both in species and individuals. It has been known for some time that in certain species of the Amiidæ the males carry the eggs in their mouths. The authors now show that this condition is more or less general. The male at the breeding season can be recognised easily by its swollen chin, the eggs being carried about packed in a dense mass. Interesting illustrations are given of the heads of some of these males carrying eggs. There are also good figures of some of the more important variations in fishes belonging to the other families described. The report deals with more than 150 species and occupies 334 pages.

Production of Hybrid Apples.—In his public lecture delivered during the British Association meeting at Bristol on Sept. 4, Sir Daniel Hall essayed, with considerable success, the difficult task of making some of the interesting genetic work of the John Innes Horticultural Research Institute intelligible to the 'man in the street'. Cultivated strains of apples, unlike many kinds of orchard fruit, are relatively self-fertile within the strain, but he showed that the proportion of fruit set per blossom, and, still more, the number of fertile seeds per fruit, is markedly lower in such well-known varieties as Ribston Pippin, Blenheim Orange, and Bramley Seedling. In these varieties, less than 30 per cent of the pollen is viable and they are particularly deficient as male parents. These varieties of

apples have now been shown to be triploid varieties with 51 chromosomes, instead of the 34, with 17 in each sex cell, characteristic of the majority of the apples. With this discovery the puzzle is rather the relatively large amount of fertile seed obtained from crosses using the sex cells of these varieties. The work of Dr. C. D. Darlington and Mr. Moffat seems to have shown a reason for this; whilst 17 chromosomes is the basic number for the genus *Malus*, as for all the genera of the Pomoideæ, in many of the Rosaceæ the basic number is 7. The relative fertility of these strains with 51 chromosomes may be explained by the fact that this basic number 7 is probably built into the genetic constitution of the apple, so that on segregation of the chromosomes, in the formation of the sex cells, whilst it is unlikely that two working sets of 17 would be separated from 51, there is the possibility of working combinations of sevens with some additional chromosomes that can be carried without disorganisation of the machinery of inheritance. In the circumstances, then, it is possible that the history of the Cox's Orange Pippin is correctly recorded; it is stated to be derived from the Ribston Pippin, but it is intelligible that successful new strains from these well-known varieties have usually been sought in vain.

Wheat-Rye Hybrids. Meister succeeded several years ago in obtaining fertile hybrids between wheat ($2n=42$ chromosomes) and rye ($2n=14$). More recently Levitsky and Benetzkaia (*Proc. U.S.S.R. Congress in Genetics, Leningrad*, vol. 2, p. 345) have examined a number of these plants in the F_4, F_5, and F_6 generations and find the somatic number of chromosomes to be 56: that is, the hybrids are amphidiploid, their chromosome number being the sum of the somatic numbers in the parent species. In the megaspore formation of the F_1 plants, it was observed that the 28 chromosomes do not pair but split, from which it is inferred that eggs with 56 chromosomes are formed and develop without fertilisation. The F_1 hybrids have always been observed to produce sterile pollen. In the later (octoploid) hybrids the pollen meiosis is frequently normal, but also shows frequent lagging and scattered chromosomes. Since the later hybrids examined all had 56 chromosomes, it is believed that gametes with extra chromosomes either fail to function or else lose them in the pollen tube formation. This doubling of the chromosomes in a sterile hybrid to produce a fertile form which breeds true is thus similar in essentials to the *Triticum-Ægilops* hybrid, *Primula kewensis*, *Nicotiana glutinosa* × *N. Tabacum* and other recent cases. Such instances offer a suggestion as to how certain genera of plants with increased chromosome number may have arisen in the past.

Ice in the North Atlantic.—The report for 1929 of the International Ice Observation Patrol Service in the North Atlantic Ocean (*U.S. Coastguard Bulletin*, No. 18) contains much interesting matter besides the record of the courses of the patrol boats and the distribution of ice. Perhaps the most significant result of several years' work is the admission that, so far at least, no satisfactory basis for the prediction of ice has been found in surface isotherms. The charts are regularly made, but they cannot be accepted as wholly reliable guides. The cold water from the melting berg appears at times to fall below warmer and lighter surface layers and thus the surface isotherms may be misleading. The problem is, however, being further studied in the hope of reaching more satisfactory results. The construction of dynamic current maps promises to be more useful, but takes more time. It is further noted that no practical way of destroying ice has yet been found. Mechanical means like blasting and mining give little likelihood of success, but it is noted that the use of thermite is rather more hopeful, were it not for the grave difficulties of placing the charge in the heart of the bergs.

Forbidden Transitions in Alkali Spectra.—Lines forbidden by the selection rule for azimuthal quantum numbers ($\Delta k = \pm 1$) have been observed in the absorption spectra of alkali metals under conditions which apparently preclude the usual explanation of this effect as due to the presence of external or ionic fields. Since it is now also recognised that the selection rule represents only approximately the content of the quantum theory of a transition, it is natural to connect these two facts, and to find from a stricter theoretical treatment of the problem the intensity to be expected for a 'forbidden' line. An analysis appropriate to the alkali metals has been developed by A. F. Stevenson in a paper in the August issue of the *Proceedings of the Royal Society*, on quadripole radiation, and by the application of the wave mechanical descriptions of these atoms which have been obtained by Hartree's method, numerical values have been calculated in a number of cases for the theoretical ratios of certain forbidden lines and normal lines. The ratio for all four alkali metals in the case of the $1S-3D$ and $1S-2P$ lines should be about 2×10^{-6}, whereas the experimental numbers, which are available only for potassium and rubidium, range from about one-half to one hundred times this, which is taken to represent a fairly satisfactory agreement in the circumstances. Other experimental evidence for the existence of quadripole radiation has also been found recently by R. Frerichs and J. S. Campbell, from the study of the transverse Zeeman effect for the auroral green line of oxygen (*Physical Review*, vol. 36, p. 152).

Restoration of Ancient Bronzes. The pamphlet with this title, published as *Museum Technique Series* No. 3 (Chicago, 1930) by the Field Museum of Natural History, contains an account by H. W. Nichols of the electrolytic process of restoration and the cure of malignant patina. The electrolytic process was devised by Prof. C. G. Fink at Columbia University. Very detailed directions are given and the pamphlet is illustrated with diagrams of apparatus and with plates showing objects before and after treatment.

The Acetylene Molecule.—The absorption spectrum of acetylene contains a number of bands arising from combined vibration and rotation of the molecule, which are in the neighbourhood of 8000 A. and so accessible to infra-red photography. Two investigations of these, which lead to a fairly complete description of the molecule, are reported in the issue of the *Zeitschrift für Physik* for Aug. 20. The first, by Prof. Mecke and K. Hedfeld, deals with the structure of the bands, and shows that the arrangement of the atoms in the molecule is linear and that if the normal separation of the atoms in the C-H group is 1·08 A., as in methane, that of the two carbon nuclei ($C\equiv C$) is 1·19 A. The distance between the carbon atoms is less than in diamond (1·54 A.) and in the diatomic carbon molecule responsible for the Swan bands (1·31 A.). The second paper, by Prof. Mecke and Dr. Childs, gives the results of a photometric analysis of the band at 7887 A. The course of the intensity changes through an absorption band furnishes considerable additional information about the structure of a molecule, and in this case is consistent with the conclusions that the electronic state concerned is that denoted by the symbol $^1\Sigma$, and that the nuclei of the carbon atoms are without spin, whilst those of the hydrogen atoms have a spin of magnitude $\frac{1}{2}$ in quantum units.

Folk and Open-air Museums.*

THOUGH the expression 'folk museum' is loosely used, it is generally understood, like 'folk-lore', to relate to the ordinary people, the rank and file of the population, the labourers, the artisans, the craftsmen, as opposed to the ruling class. Such collections of indigenous products have great historical value. They deserve to be regarded as almost the only means of preserving visible records of the national characteristics. The humbler the art or the handicraft, the more important it is from this point of view.

In England it is only recently that the regrettable disappearance of the outward and visible signs of the inner history of the people has been fully realised, and consequently it is only recently, and owing to the very rapid growth of local museums, that systematic attempts have been made and are being made to preserve them. The example for this systematic effort was set in Sweden by Dr. Arthur Hazelius, the founder of the Nordiska Museum, which is now one of the glories of Stockholm. This great scheme has been an inspiration for all subsequent attempts to illustrate fully the life of past ages.

It is important, however, to make a clear distinction between two quite different things, although they are adjacent and form part of one scheme in Stockholm. The first is the 'open-air museum' of the Skansen type, in which are re-erected the primitive dwellings, huts, cottages, workshops, windmills, bakehouses, ancient churches, and so on, that would otherwise have been destroyed or converted to other uses; and in these are generally placed the furniture, the appliances, and the decorations that belong to them. The second is the 'folk museum', which contains materials illustrating bygone life and thought at different periods or in different districts of the country; but these materials are not placed in their proper setting, they are brought together and exhibited according to purpose or material, and generally displayed in museum cases in such a sequence as either to compare the customs and handicrafts of one district with those of another, or to illustrate the development of an art or an industry. The open-air museum and the folk museum supplement each other.

There is, in addition, another sort of collection often included under the name 'folk museum', namely, the old house preserved in its original form and in its original place, and containing a display of contemporary furniture and household equipment. There is yet another type of dwelling, namely, the old house or cottage preserved in its primitive simplicity so as to present the appearance of an inhabited dwelling without anything of the museum about it; such is Ann Hathaway's Cottage. It is of such buildings that an 'open-air museum' partly consists.

Let us then confine the term 'open-air museum', for lack of a better, to the Skansen type, 'folk museum' to the Nordiska type, and let us further distinguish between the 'period museum', an old house filled with contemporary exhibits, and the 'period house' or 'period cottage', which has no museum exhibits but reproduces domestic life.

Finally there is the 'period room', either an original transported from a house which has been destroyed, or a facsimile, in which an attempt is made to reproduce the conditions of life, whether in a mansion or in a cottage. Such rooms generally constitute a separate exhibit in a museum.

* Abridged from a paper contributed by Sir Henry Miers, F.R.S., to a discussion on "A Proposed National Folk Museum", in Section H of the British Association at Bristol on Sept. 4.

STATE OF AFFAIRS IN THE BRITISH ISLES.

1. *Open-air Museums.*—In 1912 an attempt was made by a group of influential persons to press the advantages of the Crystal Palace grounds as an ideal site for such an open-air exhibit of a national character. Possibilities for local exhibits of this type have been considered, but nothing has materialised.

Recently the Report of the Royal Commission on National Museums and Galleries has considered the subject from the national aspect and has definitely recommended that a national open-air museum should be established in London; two appropriate sites mentioned are the Botanic Gardens in Regent's Park and the grounds of Chiswick House.

The question has since been taken up by a joint committee initiated by the Royal Anthropological Institute and containing representatives of the Royal Society, the Royal Society of Arts, the Museums Association, and the British Association. This committee has unanimously recommended the Botanic Gardens site as the most suitable, and has approached the Government departments concerned, urging that early action should be taken.

2. *Folk Museums.* Institutions wholly devoted to this subject, like the Nordiska Museum, are also unknown in the British Isles. The fine collection of peasant arts made by the late Master of the Charterhouse is now an annexe to the Educational Museum at Haslemere and is mainly concerned with northern Europe.

3. *Period Museums.*- Of these we have a considerable number, but comparatively few of them relate to the life of humbler folk. I may instance the Priest House at West Hoathly, the Ancient House at Thetford, the Greenland Fishery at King's Lynn, as typical examples.

4. *Period Cottages.* As a good example may be mentioned Ann Hathaway's Cottage, but very few cottage-dwellings have been preserved free from the museum taint: most of them contain showcases.

5. *Period Rooms.*—Most of these again, as at Norwich and elsewhere, are typical of the life of wealthy and cultured folk. In the National Museum at Cardiff, in the Museums at Salisbury, St. Albans, and perhaps elsewhere, attempts have been made to reconstruct a kitchen or some living-room with its appropriate furniture and utensils.

6. *Folk (Museum) Exhibits.*—Of these there are abundant examples, rich in valuable material gathered together either as local 'bygones' or placed among ethnographical collections. Conspicuous are the Pitt-Rivers Museums at Farnham and Oxford, the collections at Huddersfield and at Hull, and many of the national and larger provincial museums, including also such local collections as those at Bedford, Luton, Newark, Bolton (Hall-i'-th'-Wood), Worthing, Lancaster.

Finally, some illustrations of the life of craftsmen may be gleaned from museums which illustrate special pursuits or handicrafts; such are, however, extremely rare in Great Britain, and almost the only one which aims at something like completeness is the Museum of Fisheries and Shipping at Hull.

From this short survey it is clear that there is a vast amount of material from which the life, arts, industries, and customs of the people might be illustrated, but it is buried in other collections. It is equally clear that the real need in Great Britain is for an English or British folk museum associated with an open-air museum.

STATE OF AFFAIRS IN FOREIGN COUNTRIES.

1. *Open-air Museums.*

Sweden.—There are museums of the Skansen type in Sweden not only at Stockholm but also in many other parts of the country. There are no less than 200 open-air collections in Sweden alone. Skansen itself contains 117 separate buildings, records 700,000 visitors in a year, and occupies 60 acres.

Sweden also possesses a number of quite small village enterprises, where a field or small group of cottages have been set aside for this purpose. One of these at Bunge, started in 1907, has since become an open-air museum of considerable importance. A special feature of this museum is the ancient burial-ground, showing various methods of burial and types of burial-stones dating from the time of the Vikings.

Norway.—There is at Oslo the Norsk Museum, which was opened in 1902 and now covers an area of 35 acres, upon which are re-erected old farm-houses of different periods, and an attempt is made to re-create old streets with houses that have disappeared or are fast disappearing. At Lillehammer there is the Sandvig Collection, which contains 75 ancient buildings.

Denmark.—At Aarhus there is Den Gamle By (The Old Town), which was started about sixteen years ago by the re-erection of a Burgomaster's house and has since grown to a considerable size.

Finland.—At Helsingfors, in the Isle of Folesön, there is a large museum, covering an area of 25 acres, which was founded in 1909; this consists of more than thirty buildings of various types and periods.

Holland.—The Nederlandsch Openluchtmuseum at Arnhem consists of 20 buildings, covering an area of 75 acres; this was opened in 1918.

Rumania.—At Cluj an excellent example of an open-air museum is being formed with the object of exhibiting the typical peasant culture of the Rumanians and other nationalities in Rumania, by means of their characteristic peasant buildings and occupations. The collections will consist of typical houses brought from each district, and in each of these houses a family from the same district will live to show the type, costume, typical customs, and occupations. In addition to the typical original buildings, it is intended to erect an open-air theatre for the purpose of peasant festivals, and so on.

2. *Folk Museums.*—Museums of this type similar to the Nordiska Museum at Stockholm, though many of them are on a small scale, exist in many other places. Examples are the Museum at Karlskrona in Blekinge, Sweden, and the Engadine Museum at St. Moritz.

CONCLUSION.

It will be seen from this how late we are in any systematic endeavour to preserve and accumulate such illustrations of peasant and artisan life in Great Britain. The folk museum should undoubtedly, where possible, be associated with and supplementary to the open-air museum. It is deplorable that so many old buildings and other survivals from past times have been irrevocably lost in recent years. But the national conscience is obviously awakening to the value of such things, and determined efforts are now being made in many quarters not only to preserve the amenities of the countryside but also to conserve the old houses and cottages which are in danger of destruction. But in too many instances the advance of town building and the alteration of the countryside threaten the actual existence of many a cottage, wind-mill, forge, or other relic of the past which might be saved and re-erected in an open-air museum. Here again, where these can be retained in their own district, that should be done, and for this purpose it is to be hoped that many localities will follow the Swedish example and preserve and maintain such structures in a local enclosure. The institution of a national enclosure should not in the least interfere with such local efforts, but should serve as an example and inspiration to towns and villages all over the country.

The International Union of Geodesy and Geophysics.

THE fourth meeting of the International Union of Geodesy and Geophysics was held at Stockholm on Aug. 15-23, though the Section of Geodesy found it necessary to begin three days earlier in order to get through a long programme of work. The meeting was very well attended, representatives of thirty countries being present and numbering more than two hundred. A number of other scientific men attended by invitation, among whom were Dr. Linke, of the Geophysical Institute at Frankfurt; Dr. E. Kohlschülter, of the Geodetic Institute at Potsdam; Dr. R. Schreiter, of Freiburg; and Dr. V. Conrad and Dr. Hopfner, of Vienna.

The opening meeting was held on Friday, Aug. 15, in the Concert Hall, where Dr. E. Trygger, the Chancellor of the Universities and chairman of the Swedish National Committee, welcomed the delegates. M. Ch. Lallemand, the president of the Union, replied and expressed the thanks of the delegates for the excellent arrangements which had been made for their comfort. The other meetings of the Union, as well as those of the Sections, were held in the Parliament House, where ample accommodation was available for all.

In the Section of Geodesy, reports were presented by the delegates of the various countries on the progress made in geodetic work since the last meeting of the Union in Prague in 1927, and a number of special points were discussed. These will be published in the *Bulletin* and the *Memoirs* of the Section in due course. Much interest was taken in the account which Dr. Vening Meinesz gave of his recent determinations of gravity at sea, made from a submarine in the neighbourhood of Java, in the Pacific Ocean, and elsewhere. A very interesting discussion took place, and a strong recommendation that work of this character should be undertaken in the Bay of Bengal and other eastern waters was approved, and was later adopted by the General Assembly of the Union.

The death of Prof. H. H. Turner, who was taken ill as he was about to deliver his address as president of the Section of Seismology, cast a gloom over its meetings, but nevertheless a large amount of useful work was done. This Section, as well as that of Geodesy, both of which have to discuss and publish a large collection of data that would not otherwise be readily available to international workers, find their resources far from adequate, and Prof. Turner's address brought the urgent needs of the Section in this respect before the delegates. The work which is being done at Oxford, as well as that under Prof. E. Rothé at Strasbourg, is in need of a fuller measure of support, and resolutions to this effect were adopted by the Section. No successor to Prof. Turner was appointed, but the vice-president, Prof. E. Oddone, was authorised to act as president for the time being.

Owing to illness, Dr. L. A. Bauer, the president of the Section of Terrestrial Magnetism and Electricity, was not present at Stockholm, but his place was taken during the meeting by the vice-president, Prof. Carlheim-Gyllenskold. Dr. J. A. Fleming, of the Department of Terrestrial Magnetism, Washington, was elected president of the Section for the coming period. An interesting series of communications were presented to the Section, in one of which the magnetic work of the international stations during the Polar Year was discussed. It was decided to publish an auroral atlas as soon as the material could be selected and brought together.

The Section of Meteorology had before it a large amount of scientific work in the form of reports and communications. The plans for the work to be undertaken during the Polar Year at the international stations were discussed. This proposal, under which a number of countries have agreed to maintain for twelve months a chain of observing stations in the neighbourhood of the Arctic Circle, and also in south polar regions, was warmly supported as being certain to provide a mass of information of the greatest value and practical importance to meteorology. Dr. Axel Wallen, director of the Meteorological and Hydrographical Service of Sweden, was elected president of the Section in succession to Sir Napier Shaw.

In the Section of Oceanography, Prof. M. Knudsen was elected president in place of Prof. Odon de Buén, who has retired.

In addition to the scientific subjects which were discussed at the meeting of the various sections, the General Assembly of the Union had before it on this occasion the revision of its statutes. These were adoped eleven years ago at Brussels, when the International Research Council and four of the Unions related to it were formed. It was then resolved that the statutes there approved should come up for revision after twelve years, when experience would have shown what modification of them was desirable. At its last meeting, in 1928, the General Assembly of the International Research Council appointed a committee to consider what modifications should be introduced into its statutes, and the draft statutes which the committee prepared were adopted in July last by the Executive Committee of the Council and recommended to the General Assembly for approval at its meeting in July 1931.

The alterations which have been proposed are in the direction of giving as much freedom as possible to the Unions to arrange their own affairs, since these bodies have grown to be active organisations for scientific co-operation. This will necessitate corresponding changes in the statutes of the different Unions, and the consideration of these at Stockholm occupied the greater part of two days. The procedure for the admission of new members was laid down, and greater freedom was given to the Sections dealing with Geodesy, Seismology, Meteorology, Terrestrial Magnetism, Oceanography, Volcanology, and Hydrology to arrange their activities. It was also agreed that they should in future be termed International Associations. An important decision was that the president of the Union should not in future hold office for a longer period than from one meeting of the General Assembly to the next, and that he should not be immediately eligible for re-election. This should assist in maintaining the international character of the organisation. It may be remarked that the same rule is already operative in six out of the seven other International Unions.

Very ample arrangements were made at Stockholm whereby the delegates might visit all the technical institutions in the city which were related to the work of the Conference, and special visits were made to the offices of the Geodetic Institute, the Observatory, the Geological Survey, the Meteorological and Hydrographical Service, and others, as well as an exhibition of instruments, etc., at the house of the Mining Corporation.

Besides the work done in the sessions of the various committees, much valuable information is interchanged by delegates at the social gatherings which take place at other times, and Swedish hospitality provided a number of occasions at which the guests could discuss matters of common interest. The City Council gave a banquet in the magnificent City Hall early in the week, and the Organising Committee invited the delegates to a luncheon so that they might make the acquaintance of each other before the work of the Conference commenced, and also to a dinner, which brought the social part of the proceedings to a close. The delegates were received at the Royal Palace by H.H. the Crown Prince and the Crown Princess in the afternoon of one of the days, and on one evening a gala performance of "Aida" was given at the Opera House. One whole day was devoted to a visit to the City and the University of Uppsala.

Those delegates who were able to remain in Sweden after the meeting at Stockholm was over were able to choose between an excursion through southern Sweden and another in the northern districts of the country. The latter was of special interest for the mining and geological information which it provided. The director of the Geological Survey took charge of it and those who were able to take part enjoyed exceptional opportunities for gaining first hand knowledge of the active development which is taking place in this part of the country.

The next meeting of the International Association of Geodesy and Geophysics will be held at Lisbon in the early autumn of 1933.

The Association of Special Libraries and Information Bureaux.

IN September 1927, at Hoddesden, a conference was held of scientific and business men in many departments of human activity, to discuss the problem connected with the collection, treatment, and dissemination of information. They had no intention of forming a permanent association, but the pressing need for the examination of these problems forced the conference to organise itself. The objects of the Association so formed are: To examine, foster, and co-ordinate the activities of research organisations, special libraries, information bureaux, and similar sources; to act as a directing agency to these sources; to develop the usefulness and efficiency of special libraries; to promote, whether by conferences, meetings, or other means, the wider dissemination and the systematic collection and use of information; and to encourage, by co-operative means, the prevention of waste due to the unnecessary duplication of the work of those engaged in research and allied results. The Association has compiled a very valuable Directory of Sources of Information, and set up an Inquiry Bureau and a Panel of Translators, expert in subject as well as language.

Recently, as the result of long consideration, the Association has decided, in the interest of the more efficient indexing of literature, to become the advocate of a particular classification scheme in order to secure uniformity of method. The special committee appointed to consider the matter came to the unanimous conclusion that the Association should adopt

the Universal Decimal Classification; and, as the result of this decision, a Joint Committee with the British Society for International Bibliography has been set up."

The annual conference of the Association of Special Libraries and Information Bureaux has already become an institution to which members look forward with pleasure as a means of discussing their problems with others having the same or different points of view. It is almost impossible for anyone interested in the collection, supply, or use of information to attend one of these meetings without taking away some new idea, or making some personal contact of value.

The seventh conference, on Sept. 19-21 last, at New College, Oxford, was not less interesting or helpful. In his presidential address, Mr. H. T. Tizard referred to the multiplication of books and the need to develop methods by which people can get access to the information they contain. He quoted Dr. Johnson's dictum that "It is indeed culpable to load libraries with superfluous books", but pointed out that the difficulty is to decide which are superfluous. Readers of the *Journal of the Chemical Society* might agree off-hand that nine tenths of its contents were superfluous, but the digest of the opinions of each fellow, asked separately what tenth he would like to keep, would probably endorse the wisdom of the Publication Committee in retaining the whole. We must make up our minds that the volume of recorded knowledge will continue to swell at an ever-increasing rate, and address ourselves more eagerly than we have in the past to making better use of it. There may be nine-and-twenty right ways of indexing. But the world does not really want more than one general system, and it is high time that there was international agreement on the subject.

Among the many interesting papers communicated must be mentioned two papers by Sir Henry Lyons on "The Display of Scientific and Technical Objects", and by Dr. F. A. Bather on "The Dissemination of Information by Exhibition and Display". Sir Henry Lyons showed how it is possible to convey a great deal of information to the visitor on a short visit by the arrangement of specimens and models to indicate the development of the idea being illustrated, and by paying attention to his physical comfort. This latter aspect was also emphasised by Dr. Bather. Dr. Prinzhorn contributed a paper on the present problem of the movement in Germany for the standardising of the forms of books and periodicals and of library methods, with reference to its wider interest and international importance. In another communication, Dr. A. Schlomann explained the organisation of the German information service on technical literature.

In view of the recent decision to recommend the Universal Decimal Classification and the subject of the presidential address, problems of classification formed one of the main themes of the meeting. In this respect a paper on "The Inadequacy of the Alphabetical Subject Index", by Prof. A. F. C. Pollard and Dr. S. C. Bradford, provoked considerable discussion. The authors showed that no existing index deals with the whole literature of any one subject or generally covers even a large percentage of the total references required by a specialist. Some remarkable examples were given, which were chosen quite at random. In consequence of this incompleteness, searchers must consult as many indexes as possible. But, as they are nearly all different, each separate system must be studied, thus wasting time and patience. Of the multifarious systems in use, those of the alphabetical class are particularly bad. The difficulties inherent in the alphabetical system of subject indexing are due to the fact that the notions to be indexed may be described in each language by a variety of different combinations of different words, any one of which may be selected for an index entry, and the alphabetical order of no series of selected combinations has any direct connexion with the relationship to one another of the notions expressed. The adoption of the principle of alphabetical arrangement amounts to the rejection of that of classification. But as related subjects are scattered throughout an alphabetical index, cross-references must be added in order to direct the searcher to other headings under which related information may be found. Consequently, most alphabetical indexes are based on an unseen classification, comprising a series of selected subject headings combined with a system of cross-references. When, however, the magnitude of a comprehensive classification of knowledge is realised, it is inconceivable that an adequate concealed classification, weighted with the overwhelming mass of necessary cross-references, could be used as the basis of an alphabetical index.

Prof. Pollard and Dr. Bradford pointed out that in the alphabetical subject-index:

1. References to related subjects must be scattered throughout the whole repertory.

1.1. There is no method of co-ordinating related references within the subject except by a complicated labyrinth of cross-references, which is difficult or impossible to elaborate with completeness, and is time-wasting for the searcher.

2. There is the danger of dissociating references to essentially the same subject by the use of synonyms.

2.1. This danger can be reduced by employing a concealed classification together with a second elaborate system of cross-references, that is, from synonyms. But as the unseen classification is inflexible and necessarily incomplete, the indexer is forced to employ terms, usually taken from the authors' titles, which do not belong to the considered classification and are unconnected with either series of cross-references.

3. Essentially unrelated references are likely to be brought together under terms that may have widely different meanings; such a term as 'Survey' may mean almost anything.

4. There is risk of assuming that an expression used metaphorically is intended literally; and

5. The use of an alphabetical system excludes the possibility of collaboration with other bibliographers, especially in different countries.

5.1. This implies the perpetuation of the present chaos of independent bibliographical effort, with a maximum of inefficiency and of labour to the searcher.

On the other hand, none of these objections is inherent in a classified index, since:

1. Related references are brought together by the classification,

1.1. and consequently cross-references within the subject are not required.

2. The classification enforces the contemplation of notions; the same subject must be indexed in the same place.

2.1. No series of cross-references from synonyms is required, since the classification is not concerned with titles,

3. apparent similarity of terms, or

4. metaphorical expressions. Thus the use of a standard classification ensures a maximum of efficiency, and

5. serves to unify the work of all those using the same system, so that their references may be brought together into a single index, which may be consulted with a minimum effort.

S. C. B.

Colloid Science applied to Biology.

THE Faraday Society met at Cambridge on Sept. 29–Oct. 1 for a general discussion on colloid science applied to biology. The occasion was arranged by the Colloid Committee of the Society with the intention of bringing together physical chemists and biologists whose interests meet on this field. The attendance was unexpectedly large, and among those present were some twenty delegates from other countries. Before the discussion began, Prof. Wo. Ostwald delivered greetings to the Society from the Colloid Gesellschaft, and Prof. H. F. Burton presented those of the Ottawa Colloid Symposium. The discussions, which extended over three days, were of sustained and exceptional interest.

The subject first discussed was introduced by Prof. A. V. Hill, whose report dealt with a proof, based upon the work of Dr. I. Straub and confirmed by experiments of his own, that although a 'living' membrane, such as that which separates the yolk from the white of an egg, may be fully permeable to water and electrolytes, thermodynamic equilibrium may never be reached across it. The membrane alters the equilibrium by the continuous performance of work. A 'steady state' is maintained, but there is no equilibrium so long as the membrane is 'alive'. Dr. Straub described experiments involving an endeavour to reproduce this condition in the case of artificial membranes. The subsequent discussions showed the biological importance of the facts involved.

In the absence of Prof. Gortner, of the University of Minnesota, his paper on the state of water in colloidal and living systems was taken as read. A discussion of great interest made clear that a definition of 'bound' as contrasted with 'free' water is not yet possible. Different methods give results so diverse that little meaning can at present be attached to the terms in question. Prof. Svedberg then summarised the results of his determinations of protein molecular weight by means of the ultracentrifuge. Twelve proteins had molecular weights of 1, 2, 3, or 6 × 34,500, while two hæmocyanins had molecular weights exceeding a million. These are constant over a pH range varying from 2 to 8 units, but may dissociate reversibly outside that range. In the discussion which followed, Prof. H. R. Kruyt and Dr. P. Lecomte du Nouy attacked the view that the aggregates the weight of which was thus determined were molecules rather than micelles consisting of numerous molecules. A very wide divergence of opinion on this point was revealed in the debate which followed.

Prof. W. Pauli, of Vienna, described very briefly his recent researches dealing with the behaviour of proteins towards other colloids and towards electrolytes; and Prof. F. F. Nord dealt with the physical influence of gases on colloids. The report of Prof. Fauré-Fremiet dealt with the physiological and physico-chemical factors involved in the active movements of amœbæ, and his remarks were followed by an instructive discussion. A report of Prof. R. A. Peters, of Oxford, giving arguments for the necessity of assuming a permanent architectural structure in protoplasm, led to many interesting expressions of opinion. The familiar difficulty of reconciling such structure with proved fluidity was well to the front. Dr. Cramer directed attention to the significance of structures such as mitochondria and Golgi apparatus; and Prof. J. B. S. Haldane, dealing well with the genes of the geneticist, argued that their history and influence suggest for them a relatively simple chemical constitution with superimposed structure—a combination, as it were, of chemical and morphological patterns.

In the report of Dr. Hans Pfeiffer, of Bremen, the question of the isoelectric point of living cells was raised; and in that of Drs. von Muralt and Edsall —very clearly presented by the former—the technique and results of a study of double refraction in muscle proteins was described. This provoked interesting comments from the physical chemists. Finally, Dr. J. H. Quastel, speaking on mechanisms of bacterial activity, referred to his own theory of molecular activation at the cell surface, and described recent experiments in which it has been found that, after complete lysis, certain dehydrogenases present in the intact cell disappear. Other enzymes, the indophenol oxidase, for example, remain intact.

The complexity of the biological field was brought prominently before the company when, during the first evening, a number of cinematograph films were shown in a theatre at the Engineering Laboratories. These included studies of living cells by Dr. Canti, and one of amœboid motion by Prof. Fauré-Fremiet. A striking film exhibited by Dr. Robert Chambers illustrated the methods of micro-dissection and micro-injection. In relation with these exhibits was a report of Dr. Honor B. Fell, of the Strangeways Research Laboratories, Cambridge, and Dr. Wilmer, on the phenomena observed during the culture of vertebrate cells *in vitro*. Part of this report was presented by Dr. Wilmer during the discussions of the following day.

On the evening of Oct. 1 the members of the conference dined together in the Hall of Pembroke College. The services of Prof. T. M. Lowry, the retiring president, were gratefully acknowledged, and his successor, Dr. Robert Mond, was warmly welcomed.

Imperial Wool Research Conference.

UNDER the auspices of the Empire Marketing Board, delegates from the Dominions, the chief wool-producing Colonies, and research institutions in Great Britain, together with representatives of Government Departments concerned, met in conference upon matters relating to wool research during the week Sept. 22-26. The meetings commenced with an address by the Right Hon. J. H. Thomas, Secretary of State for the Dominions, who welcomed the delegates and expressed the hope that from the deliberations of the conference the progress of research into the production and utilisation of wool throughout the Empire might be stimulated.

Mr. A. L. Hetherington, of the Department of Scientific and Industrial Research, gave a brief outline of the industrial research associations in Great Britain, mentioning especially the position occupied by the British Research Association for the Woollen and Worsted Industries at Torridon, Leeds. Dr. S. G. Barker followed with a paper on scientific correlation between producer and manufacturer, in which he discussed the difficulties of the manufacturer in dealing with wool in the production of which he was not interested or associated, and of the producer who lost interest in his product so soon as he had completed the sale of it and had had it removed from his premises. He stressed the important point that of all animal products wool alone has to pass through

a definite series of manufacturing processes before the finished article made from it is absorbed into commerce, and the further important point that while the producer's unit is to all intents and purposes the fleece, with the broker's 'sorting' and the manufacturer's further 'sorting' the fleece loses its identity long before it reaches a stage where any particularly desirable or undesirable quality can be recognised. This means that it is exceedingly difficult, other than in a very general way, for the manufacturer to express his views in terms that can readily be understood by the producer. Guidance in breeding, feeding, or sheep husbandry for the improvement of the wool produced cannot emanate from the trade organisations representing the manufacturers without some liaison, which could best be provided by a series of scientific research institutions correlated together and cognisant of conditions both of wool production and utilisation. The threat of a revolution in the wool industry based upon the discovery of a method of elaborating a form of artificial wool fibre, which may replace the natural material to a degree equivalent to or greater than that which has occurred in the silk industry, demands that there be a greater correlation between the producer and the manufacturer for the security of each. Such a correlation, in Dr. Barker's opinion, can only come from a thorough understanding of the chemical, physical, biological, and other factors concerning wool itself.

There followed accounts of the results of recent research work and of work in progress in Australia, South Africa, New Zealand, and Canada. The impression gained was that the production of finest quality manufacturing wools is still essentially a monopoly of Australia and South Africa, but that further development is limited, first, by climate and environmental difficulties, and secondly, by the economic menace of the chief competitor of wool, namely, mutton. It would seem that as the large sheep-walks are broken up and more intensively grazed, so does the stock-carrying capacity of the land increase, until there comes a time when in the natural evolution of arable from grazing land the owner is compelled to turn his attention to mutton production, at the expense of his wool quality, the ideal dual-purpose sheep not yet existing.

In the extension of the sheep-walks on to unsettled land, two important limiting factors must be overcome—the deficiency of phosphorus and the inadequacy of a natural supply of protein. It would appear that South Africa's more pressing problem is the provision of a phosphorus compound in a cheap, readily assimilable form, and to this Australia adds that particular sulphur-containing protein which shall eventually prove to be most suitable for the needs of the sheep—but both would welcome a more regular and even rainfall.

Dr. J. E. Nichols reported briefly and in general upon his recent survey of the wool-producing parts of the Empire. He spoke from the production end of the wool industry and indicated the factors arrayed against the production of a uniformity of fibre which would be regarded by the manufacturer as ideal. He stressed the individuality of the sheep farmer and the variety of the environmental conditions under which he works, the variation in breed, in breed type, between individuals, and even in fleeces. He indicated the economic result of producing an article like wool, which is entirely absorbed, including off types, by-products, and waste, away from the farm by the manufacturer.

The most pressing problems in the production of wool are not those of nutrition or disease of the sheep, important though these may be for any one generation, but are problems of genetics and breeding. Only by breeding on sound lines will real successive improvements or the maintenance of excellence in a stock community be achieved.

The delegates then visited Leeds, where, between the regular sessions for discussion, they had an opportunity to see the work in progress, chiefly on the manufacturing side of wool research, both at Torridon and at the Textile Department of the University of Leeds. They also visited, during the week, the Bradford Technical College and the Bradford Conditioning House.

The last session of the conference was held in Edinburgh, at the Animal Genetics Department of the University, where papers relating solely to the biology of the fleece and the physiology of wool production were discussed. The delegates were shown the methods adopted to throw light upon the purely fundamental problems of wool production from physiological and genetical aspects.

At the final meeting, certain resolutions were passed, and these will be reviewed by the Research Sub-Committee of the Imperial Economic Conference now in session.

University and Educational Intelligence.

BIRMINGHAM.—The following appointments to the lecturing staff have been made: Dr. G. E. Harrison (physics), Dr. C. R. Porter (chemistry), Mr. H. M. Bateman (civil engineering), Mr. W. E. Isaac (botany), and Mr. N. M. MacElwee (mining electrical engineering).

Mr. D. J. Cameron has been appointed Registrar in succession to the late Mr. J. H. Costain.

The Wardenship of Chancellor's Hall (vacant by the retirement of Prof. F. Tillyard) has been filled by the appointment of Major Robert C. Panton.

LONDON.—In recent years science courses have not been in very great demand in University Extension work in London, but the current programme issued by the University shows that lectures on scientific subjects are coming again into popular favour. Foremost amongst the courses arranged is a series of twenty-four lectures by Prof. D. M. S. Watson on modern ideas and work in zoology, which are being delivered on Monday evenings at Gresham College, Basinghall Street. The time of the lectures—six o'clock—should prove ideal for those city workers who are interested in this subject and desire to hear of the most recent advances and the outlook for the future. Courses in evolution, heredity, and biology are being given by Mr. G. C. Robson in such widely separated parts of London as New Cross, Stratford, and Woolwich; and Mr. Barratt Brown is conducting an introductory course in psychology at the Mary Ward Settlement on Friday evenings. Details regarding these and other courses may be obtained from the University.

THE Trustees of the Busk Studentship in aeronautics, founded in memory of Edward Teshmaker Busk, who lost his life in 1914 whilst flying an experimental aeroplane, have awarded the studentship for the year 1930–31 to Mr. R. H. Francis, of the University College of North Wales, Bangor.

A SPECIAL course of lectures on "Some Newer Therapeutic Agents: their Pharmacological Identification and Tests, with some Account of their Uses in Medicine" will be given by Dr. J. H. Burn, director of the Pharmacological Laboratories, Pharmaceutical Society of Great Britain, in the Society's Lecture Theatre, 17 Bloomsbury Square, on Monday, Oct. 13, and succeeding Mondays, at 5.30 P.M. Admission to the first lecture is without ticket.

Historic Natural Events.

Oct. 13, 1913. Low Temperature in the Upper Air.—It has been known for many years that at high levels over temperate and equatorial regions the temperatures of the air are far lower than any ever recorded on the earth's surface. The lowest known temperature above the British Isles is −98° F. which was recorded by a balloon carrying a small meteorograph, at a height calculated as 7·8 miles (12·5 km.) above Pyrton Hill, on Oct. 13, 1913. Still lower temperatures have been recorded over equatorial regions, the minimum being −133° F. at a height of 10·6 miles (17 km.) above Batavia, Java.

Oct. 13–14, 1881. Great Storm over British Isles.—This was one of the most severe gales of the second half of the nineteenth century in the British Isles. A very deep depression travelled in an east-north-east direction across the extreme north of Ireland and the south of Scotland. The storm caused great loss of life at sea, 108 vessels being posted at Lloyd's in one day, and there was also much damage on the land, especially in the south of Scotland and the north of England. In London the gale caused eight deaths.

Oct. 14, 1755. Red Fog and Red Snow in Locarno.—In Locarno a very hot wind blew with a red fog, followed by blood rain; in the Alps red snow fell accompanied by violent thunder. This was evidently a strong *Föhn* carrying dust from the Sahara.

Oct. 15, 1811. Comet.—During the autumn of 1811 the great comet in the night sky was an arresting object with its bright nucleus and curved tail that was 26° in length (equivalent to 100 million miles) and 5° broad on Oct. 15. This comet, of the exceptional duration of visibility of seventeen months, was one of the most memorable of the nineteenth century. It is described by Sir William Herschel in *Phil. Trans.*, p. 115-143; 1812.

Oct. 15, 1885. Gale at Partenkirchen, Bavaria.—A barometric depression travelled northwards from the Sahara, and a *Föhn* blew in the Partenkirchen Valley, increasing in force until 7 P.M. From 5 to 8 P.M. the storm was the most destructive known since 1821–22. Houses were unroofed, windows were blown in, and a million large trees were uprooted. The rain which accompanied the storm left a yellowish-red deposit, presumably sand from the Sahara. Temperature rose rapidly from 37° to 70° F., and the melting of the snow, combined with the heavy rainfall, caused serious flooding in the Inn.

Oct. 16–19, 1848. New Zealand Earthquakes.—Three great earthquakes were felt, chiefly near the north end of the South Island, on Oct. 16, 17, and 19. Besides the ordinary fissures in the surface soil, a remarkable fracture ran for 60 miles from Cloudy Bay in Cook Strait in a south-south-easterly direction, keeping always parallel to the neighbouring mountain-chain.

Oct. 16, 1913. Heavy Rain in Malta.—Very heavy rain fell over the island of Malta, the amount recorded in 24 hours reaching 16·30 in. at Vittoriosa. At Valletta the fall was 12·56 in., of which 6 in. fell between noon and 3 P.M. The rainstorm was accompanied by violent wind and destructive lightning.

Oct. 17, 1091. Gale in London.—According to the "Anglo-Saxon Chronicle": "Much harm was done in London with an outrageous wind, the violence whereof overturned and rent in pieces above four hundred houses, at which time and tempest the roof of St. Mary Bowchurch, in Cheap, was also overthrown, wherewith two men were slain. Moreover at Salisbury much hurt was done with the like wind and the thunder for the top of the steeple and many buildings besides were sore shaken and cast down."

Oct. 18, 1907. Visibility of Mont Blanc.—An exceptional example of visibility occurred at Dijon on Oct. 18, 1907. As the train left Dijon station, Mont Blanc could be seen very clearly above the chain of the Juras, apparently suspended in the air, only the snow-covered summit emerging. It remained visible until Mâcon was reached. The day was overcast, but the atmosphere was extraordinarily clear, after several weeks of continuous rainfall. The normal limit of visibility of Mont Blanc is 115 miles, and it is extremely rarely seen from the low level of Dijon station 139 miles distant.

Societies and Academies.

LONDON.

Society of Public Analysts, Oct. 1.—G. W. Baker: Scientific evidence relating to firearms, with special reference to a recent murder trial. Scientific methods of investigation were used in examining the bullet and cartridge case found on the scene of a murder in Jerusalem in August 1929. X-ray photography showed that the piece of a bullet found in one of the bodies was British ammunition, and that it had been fired from a rifle of the same calibre and rifling as that of the accused. Photomicrographs showed that the cartridge case found on the scene had at least fourteen marks on the pin impression, all of which were found on the firing pin of the rifle. The extractor mark was also a very characteristic feature.—**J. W. Croxford**: The composition of rye oil. Two samples of rye, a sample of Ryvita crispbread, and a sample of rye flour, extracted by means of petroleum, yielded about 2 per cent of oil. It was semi solid, contained 8-10 per cent of unsaponifiable matter, had chemical characteristics similar to those of maize oil, and behaved like a semi drying oil. It has little, if any, vitamine activity.—**G. E. Lester Smith**: The determination of unsaponified oil in soap or fatty acids. Modifications of the 'emulsion test', in which the presence of oil in fatty acid is indicated by the turbidity of a solution of the ammonium soap in dilute alcohol, are described. So little as 0·05 per cent of oil can be detected. The test may be made quantitative by a determination of the volume of water required to produce incipient turbidity in an alcoholic solution of the ammonium soap under standard conditions.

CAPE TOWN.

Royal Society of South Africa, July 16. Sir Thomas Muir: Note on Brioschi's bordered Hessian.—**S. H Haughton**: Mammoth and elephant teeth from the Vaal River gravels. Nearly every elephant tooth discovered in these gravels has been made the type of a separate species; molars of individuals of the existing African elephant from a single locality show a large amount of variation, and this should be considered in the discussion of the status of fossil forms.—**P. R. v. d. R. Copeman**: Changes in the composition of oranges during ripening. During the period of ripening, the total weight of the orange increases. During the final stages of growth, the effects of transpiration become dominant, causing a loss in weight due to loss of water, which is accompanied by an increase in the concentration of the soluble solids in the juice. There was no significant increase in the nitrogen content or ash content of the juice. The changes in the soluble solids and sugars can be expressed by means of an equation representing an autocatalytic reaction. The changes in the cell-wall material and in the acidity can be expressed by means of a logarithmic curve. Arsenate spray exerts an internal physiological action as a result of which there is a selective oxidation of the respiratory materials in the fruit.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, Vol. 16, No. 7, uly 15).—**Linus Pauling**: The structure of some odium and calcium aluminosilicates. The electro-;atic valence rule suggests that aluminium ions in uch salts have the co-ordination number 4, the oxygen oms being common to a silicon tetrahedron, an aluminium tetrahedron, and one or more alkali-ion polyedra. Sodalite, natrolite, the scapolites, and davyite-cancrite have such a structure. It provides, in he zeolite natrolite, channels along (001) planes such hat water can escape without rupturing the frame-vork, and sodium ions pass out as other cations enter o replace them (base-exchange). **Arnold Rice Rich**: 'he demonstration that allergic inflammation is not ecessary for the operation of acquired immunity. After recovery from infection, the body is often highly esistant to the same infectious agent but is extremely ensitive to products of disintegration of the bacteria, which readily produce local damage and severe inflammation (hypersensitive or allergic inflammation). 'ontrary to general opinion, active immunity in yphilis and passive immunity to the pneumococcus re not dependent on allergic inflammation; the spread of pneumococcus is inhibited primarily by a pecific agglutinative process which precedes inflammaion. It is suggested that allergy should be abolished y desensitisation in diseases such as tuberculosis, n which it causes untoward symptoms. **Willem . Luyten**: On the systematic and accidental errors of nodern trigonometric parallaxes. **W. de Sitter**: On he distances and radial velocities of extra-galactic iebulæ, and the explanation of the latter by the relaivity theory of inertia. A theoretical discussion leading to the view that the dynamical solution of the field equations of the general theory of relativity accounts or the expansion of the universe, which is homogeneously filled with matter and has spherical symmetry hroughout its history. **S. S. Cairns**: The cellular livision and approximation of regular spreads. **Harry Levy**: Normal co-ordinates in the geometry of paths. **W. A. Marrison**: The crystal clock. Consists essenially of a constant frequency generator controlled by a quartz crystal resonator. The crystal is in the form of a ring with the plane of the ring parallel to the optic and electric axes, and is so shaped that its temperature coefficient is as near to zero as desired at a given temperature. The clock can be used to give continuous ndication of time, accurate timing signals, or continuous and accurately controlled motion. So far as is known, it is not affected by gravitational and magnetic fields. —**Oliver R. Wulf**: The band spectrum of ozone in the visible and photographic infra-red. Ozone-oxygen mixtures from a silent discharge ozoniser were examined in a tube 2·5 cm. in diameter and 33 metres long. The bands observed are diffuse, suggesting predissociation of the ozone molecule, and there appears to be a weakening of the weak bands with respect to the strong bands with reduction of temperature. This suggests a means of determining the temperature of the atmosphere at the ozone layer.—**Richard C. Tolman**: On the estimation of distances in a curved universe with a non-static line element. Using the line-element determined in earlier papers, a relation is obtained between angular extension and luminosity of nebulæ which should be just within the range of observational verification. —**William Rowan**: Experiments in bird migration. (2) Reversed migration. Juncos were submitted to artificial illumination after dusk, so as to simulate increasing length of days; the gonads increase in size and at a certain period appear to release a hormone, which causes migration. They are small birds and protected by law, so in an attempt to verify these findings and to determine the direction of migration which ensues, crows were used. The numbers available were limited but the results suggest that the enlargement of gonads which occurs under artificial illumination leads to a northward migratory movement, similar to that shown by the birds in the free state with the approach of summer. Controls (with gonads practically at minimum) tended to remain at Edmonton, Alberta, when liberated in winter, although crows normally have gone south at the end of summer.

FRIDAY, OCTOBER 10.

ROYAL SANITARY INSTITUTE (in the Guildhall, Nottingham), at 4.30.—Alderman A. R. Atkey: River Pollution.—Dr. L. P. Lockhart: Industrial Medicine in Relation to Public Health.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.

IRON AND STEEL INSTITUTE (Joint Meeting with the Local Branch of the South Wales Institute of Engineers) (at the Royal Metal Exchange, Swansea), at 7.—A. Kříž: The Heterogeneity of an Ingot made by the Harmet Process.—H. C. Wood: Open-hearth Furnace Steelworks: a Comparison of British and Continental Installations and Practice.—O. Quadrat: A Contribution on the Problem of the Analysis of Basic Slags and the Representation of their Composition in a Triangular Diagram.

OIL AND COLOUR CHEMISTS' ASSOCIATION (Manchester Section) (at Milton Hall, Manchester), at 7.—N. Heaton: Some Possibilities of Inorganic Paint Vehicles.

MANCHESTER ASSOCIATION OF ENGINEERS (at Engineers' Club, Manchester), at 7.15.—G. E. Windeler: Thermal Progress (Presidential Address).

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—S. Dunlop: The Refining of Cane Sugar.

KEIGHLEY ASSOCIATION OF ENGINEERS (at Queen's Hotel, Keighley), at 7.30.—T. H. Turner: Materials Used in Modern Engineering.

INSTITUTE OF METALS (Sheffield Local Section) (in Mappin Hall, Applied Science Department, University, Sheffield), at 7.30.—Prof. F. C. Thompson: Some Observations on the Wire Drawing Process (Sorby Lecture).

RAILWAY CLUB (at 57 Fetter Lane), at 7.30.—C. J. Allen: Notes on Time Tables and Train Running.

ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30.—E. W. Brewerton: Presidential Address.—Dr. F. W. Edridge-Green: The Detection of Colour Blindness from a Practical Point of View.

SATURDAY, OCTOBER 11.

INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch, Burnley Section) (at the Technical College, Burnley).—F. Griffiths: Belgian Moulding Sands in the Iron Foundry.

MONDAY, OCTOBER 13.

INSTITUTE OF TRANSPORT (at Institution of Electrical Engineers), at 5.30.—Hon. Sir Arthur Stanley: Inaugural Address.

INSTITUTION OF AUTOMOBILE ENGINEERS (Bristol Centre) (at Merchant Venturers' Technical College, Bristol), at 7.—Sir Herbert Austin: The Future Trend of Automobile Design (Presidential Address).

BRADFORD TEXTILE SOCIETY (at Midland Hotel, Bradford), at 7.30.—A. Highley: Presidential Address.

MEDICAL SOCIETY OF LONDON.—Dr. R. A. Young: The Stethoscope, Past and Present (Presidential Address).

SOCIETY OF MOTION PICTURE ENGINEERS (London Section) (at Royal Photographic Society).—P. Smith: Kinephotomicrography.

TUESDAY, OCTOBER 14.

INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—H. S. Glyde: Experiments to Determine Velocities of Flame Propagation in a Side Valve Petrol Engine.

INSTITUTE OF MARINE ENGINEERS, at 6.—O. Wans: The Design and Manufacture of Marine Auxiliary Oil Engines.

INSTITUTE OF METALS (North-East Coast Local Section) (in Electrical Engineering Lecture Theatre, Armstrong College, Newcastle-upon-Tyne), at 7.30.—C. Gresty: Chairman's Address.

ROYAL SOCIETY OF MEDICINE, at 8.30.—Dr. C. Jackson: Suppurative Diseases of the Lungs (Lecture).

WEDNESDAY, OCTOBER 15.

SOCIETY OF GLASS TECHNOLOGY (at Sheffield), at 2.

INSTITUTION OF ENGINEERING INSPECTION (at Royal Society of Arts), at 5.30.—E. Harle: A Practical Application of British Standard Limits and Fits to Locomotive Construction.

ROYAL MICROSCOPICAL SOCIETY (at B.M.A. House, Tavistock Square), at 5.30.—J. E. Barnard: Demonstration by Micro-Projection of some Histological Preparations from the Society's Collection.—Dr. G. M. Findlay: Some Recent Research on Malarial Parasites.

NEWCOMEN SOCIETY FOR THE STUDY OF THE HISTORY OF ENGINEERING AND TECHNOLOGY (at Science Museum, South Kensington), at 5.30.—H. P. Vowles: Enquiry into Origins of the Windmill.

INSTITUTION OF ELECTRICAL ENGINEERS (South Midland Centre) (at Grand Hotel, Birmingham), at 7.—Prof. W. Cramp: The Birth of Electrical Engineering (Faraday Lecture).

SOCIETY OF RADIOGRAPHERS (in Reid-Knox Hall, Welbeck Street), at 7.—C. L. Winch: Presidential Address.—Dr. E. C. Jorman: Address.

HALIFAX TEXTILE SOCIETY (at White Swan Hotel, Halifax), at 7.30.—L. le Conteur: Safety and Welfare in Factories.

ELECTROPLATERS' AND DEPOSITORS' TECHNICAL SOCIETY (at Northampton Polytechnic Institute), at 8.15.—J. W. Cuthbertson: Practical Difficulties in the Electrodeposition of Chromium.

THURSDAY, OCTOBER 16.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Joint Meeting of Pictorial and Kinematograph Groups), at 7.

SOCIETY OF CHEMICAL INDUSTRY (Nottingham Section) (at University College, Nottingham), at 7.30.—Dr. J. B. Firth: Some Methods of treating Trade Effluents.

OPTICAL SOCIETY (at Imperial College of Science and Technology), at 7.30.—R. L. Smith: The Vickers Projection Microscope.—Demonstrations of The Vickers Pyramid Hardness Testing Machine, C. Baker's Works Projection Microscope, and C. Baker's Brinell Microscope.

INSTITUTION OF WELDING ENGINEERS (at Institution of Mechanical Engineers), at 7.45.—P. L. Roberts: The Replacement of Castings by Weldings.

CHEMICAL SOCIETY, at 8.—Ceremony of the Unveiling of the Perkin Memorial Plaque.—Prof. W. N. Haworth: Oration on the Life and Work of the late Prof. W. H. Perkin.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at 11 Chandos Street, W.1), at 8.15.—Dr. F. Marsh: The Etiology of Heat Stroke and Sun Traumatism.

BRITISH INSTITUTE OF RADIOLOGY (in Reid-Knox Hall, Welbeck Street), at 8.30.—Dr. J. F. Bromley: The Use of Negative Paper.—Capt. A. J. Wood: Ultra-Violet Glasses.—G. Simon: The Use and Technique of Diathermy in the Treatment of Pneumonia.

INSTITUTE OF BREWING (Midland Counties Section) (at White Horse Hotel, Birmingham).—S. Myer: The Season's Hops.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Tees-side Branch) (at Middlesbrough).

FRIDAY, OCTOBER 17.

PHYSICAL SOCIETY (at Imperial College of Science), at 5.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—L. St. L. Pendred: Presidential Address.

IRON AND STEEL INSTITUTE (Glasgow Section, jointly with West of Scotland Iron and Steel Institute) (at Royal Technical College, Glasgow), at 7.15.—R. Hamilton: Presidential Address.—Discussion on papers by H. C. Wood: Open-hearth Furnace Steelworks: a Comparison of British and Continental Installations and Practice, and J. Šarek: What Reasons compelled the Prague Ironworks to Introduce Thin-walled Blast-furnaces.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—T. H. Flowers: The London Automatic Telephone System.

SATURDAY, OCTOBER 18.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 4.—Prof. J. B. Leathes: Harveian Oration.

PUBLIC LECTURES.

SATURDAY, OCTOBER 11.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. W. G. Ivens: Native Life in the Solomon Islands.

MONDAY, OCTOBER 13.

UNIVERSITY COLLEGE, LONDON, at 5.—Dr. H. P. Gilding: The Reticulo-Endothelial System. (Succeeding Lectures on Oct. 20, 27, and Nov. 3.)—At 6.30.—Miss M. S. West: The Comparative Study of the Religions of the World (Introductory Lecture).

TUESDAY, OCTOBER 14.

KING'S COLLEGE, LONDON, at 11 A.M.—S. P. Turin: The Economic Geography of U.S.S.R.: Area, Territory, Climate, Vegetation, Mineral Resources.

BEDFORD COLLEGE, at 12 noon.—Miss Tarrant: History of Greek Philosophy.—At 3.—Prof. Spencer: History of Chemistry.

UNIVERSITY COLLEGE, LONDON, at 5.30.—Prof. C. Spearman: Psychologies of To-day (Introductory Lecture).—J. H. Welweg: Danish Castles and Manor Houses. (Succeeding Lectures on Oct. 22 and 29.)

WEDNESDAY, OCTOBER 15.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Dr. E. Graham Little: The Prevention of Accidents, Disorders and Disease in Members of the Medical and Nursing Professions.

ROYAL ANTHROPOLOGICAL INSTITUTE (in Portland Hall, Regent Street Polytechnic Extension, Little Titchfield Street, W.), at 5.30.—Prof. J. L. Myres: Native Races of the Empire: Facts and Problems.

KING'S COLLEGE, LONDON, at 5.30.—Sir Humphry Rolleston, Bart.: Medicine.

THURSDAY, OCTOBER 16.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Dr. C. K. Millard: Contraception and the Medical Officer of Health.

KING'S COLLEGE, LONDON, at 5.—Dr. J. A. Hewitt: Metabolism of the Carbohydrates and Fats. (Succeeding Lectures on Oct. 23, 30, and Nov. 6.)

KING'S COLLEGE, LONDON, at 5.15.—Miss C. Maxwell: Chateaubriand and the French Romantics.

UNIVERSITY COLLEGE, LONDON, at 5.30.—Prof. E. G. Gardner: The Psychology of Dante.

SATURDAY, OCTOBER 18.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Prof. J. R. Ainsworth Davis: The Uses of a Tail.

CONGRESSES.

OCTOBER 13 TO 16.

CONGRESS OF THE ITALIAN SOCIETY OF SURGERY (at Rome).—Discussions on Treatment of Cranio-cerebral Trauma apart from Gunshot Wounds; Diagnosis and Treatment of Hæmaturia.

OCTOBER 15 TO 23.

INTERNATIONAL CONGRESS OF HYDROLOGY, CLIMATOLOGY, AND MEDICAL GEOLOGY (at Lisbon).

OCTOBER 20 TO 23.

FRENCH CONGRESS OF HYGIENE (at Paris).—Discussions on Successive Changes in French Pharmacopœias, Comparative Statistics of Infantile Mortality, Study of the Reports of Health Offices, Hygiene and Reconstruction in the Inundated Districts in the South of France, and Lectures on Psittacosis, by Prof. Sacquépée, and on Lavoisier as Hygienist, by Dr. Dujarric de la Rivière.

SATURDAY, OCTOBER 18, 1930.

Industrial Localisation.

DURING recent years close study has been made by the Ministry of Labour, and in other quarters, of labour mobility and transference, and of the various factors entering into the establishment of new industries and the progress or decline of old ones in different localities, matters which may be grouped for convenience under the heading of industrial localisation. This may cover also a comparison of the respective merits of specialist localities, having only one principal industry on which they depend almost wholly for economic life, and diversified localities with several different industries.

A complete discussion of industrial localisation —why a certain trade, or group of trades, settles in one particular locality, why some decline and fall, others are stationary, and others, again, thrive and prosper, of all the varied and complex conditions, indeed, which govern the well-being of industry from the point of view of site selection—this is one of the most important chapters in the economics of industry to-day. No doubt it attracted some attention years ago, at the hands of writers like Marshall, for example; but it has now assumed more than academic importance, and has been well to the fore in most discussions of the dark and intractable problem of unemployment. It is perhaps one of the few avenues where a gleam of hope and light is seen in the far distance.

In approaching unemployment, somewhat wearily at times but yet undaunted, it is of particular interest to note the vital and significant fact that a few districts in Great Britain—one or two of them very extensive—have been much less afflicted with unemployment than the rest of the country. This is doubtless well known to many, but it has been more definitely and clearly demonstrated and set on a more impressive statistical basis by recent investigations than was formerly the case. It is well worth while, however, to consider this matter a little further in its various implications, to inquire a little more closely into the reasons why some parts of the country are so much more fortunate in this respect than others, and, what is of considerable practical importance, to consider whether these favourable conditions can be reproduced elsewhere with similar results on labour demand.

A concrete illustration of fairly successful emergence from the general flood of adversity is afforded by Birmingham and surrounding country.

The incidence or intensity of unemployment may of course be studied by reference to individual trades or individual localities: numerous studies have recently been made of both sorts and a vast amount of statistical material is now available, so that the main issues of the problem are like to be obscured and overwhelmed by a superabundance of such material; but it is difficult to isolate either districts or industries completely, and it is proposed here to consider briefly a large area comprising a great multiplicity of different industries and to examine the suggestions which emerge.

The industrial history of Birmingham and its environs is well known. In 1870 it was mainly engaged in coal-mining, iron manufacture, and numerous hardware trades, but in the great depression which set in about 1874 profound changes took place; many of the older industries declined, some almost to the point of extinction, whilst other new ones took their place, including those connected with the manufacture of bicycles, motor vehicles, and many branches of the rubber, electrical, food, drink, and other trades. The net result is that this part of England has carried out a movement in labour transference on a tremendous scale during the last ten or twelve years—much of it indeed began before the War, so long ago as 1875—and has suffered much less from labour surplus than the rest of the country, with the exception of one or two other areas somewhat similarly circumstanced though on a smaller scale.

The reasons for this are complex and in part obscure, and the usual causes assigned for industrial selectivity are inadequate; or at all events, though we may say that the direct and immediate cause consists in the great diversity of manufactures, it yet remains to ask the reason of this great diversity. It is certainly the case that some areas are specialised and dependent on practically one trade only, and others are diversified and have numerous different trades. Why is this so, and, more particularly, can specialised areas be converted into diversified ones consciously and in accordance with definite planning and co-ordination by Government or other bodies, and thereby reap the same benefits?

The tendency to-day will probably be towards an affirmative reply to the latter query, and it marks a profound change in the modern attitude towards every part of the economic realm. Formerly it was customary, and even regarded as truly scientific and philosophical, to regard economic and industrial phenomena and changes as due to the operation of certain fundamental laws, for the most part inevitable and inexorable: the biological or evolutionary view of society held the field, and governed *inter alia* the localisation of industry. Now we are more disposed to exchange the biological for the architectural and to assert boldly that a nation can consciously build up its economic fabric, going from strength to strength, and perhaps even take some account of beauty in design and form.

The task of construction, however, becomes constantly more difficult and complex, and much, both of the difficulty and complexity, arises from the fact that the political machinery has not even yet been brought sufficiently up-to-date, or inspired with adequate sympathy and knowledge, to realise and deal with the real needs and problems of modern industry. The scientific worker and technologist, it is true, now play a large and prominent part in many departments of government; but this part is still subordinate and the highest ranks of government officials are still dominated by a type of mentality which is certainly not that of the keen alert statesman, trained in business and fully alive to the needs of industry. The political destinies of a great nation have now become so largely dependent on economic and technical factors that it is quite impossible to separate politics from economics: they are now almost one and inseparable, for no industrial problem to-day can be treated apart from its political background and environment.

Reverting, after this brief digression, to the particular aspect of social architecture with which we are dealing, that of industrial localisation, we have found, from the examples of Birmingham and district and one or two other cases, that a diversification of industries—in these cases at least—has reduced the incidence of unemployment. Can we legitimately deduce therefrom a general rule, or is it only applicable in certain narrowly defined areas?

Prof. G. C. Allen, of University College, Hull, in a recent issue of the *Economic Journal*, very ably discusses the particular case of Birmingham and surrounding country, and finds that, where diversified industry is already in existence, it tends to attract additional enterprise and new industries owing to the advantages derived from such variety, among which the chief is that of greater alertness in workers and employers, greater keenness to seize opportunities, and a wider range of technical skill. He does not, of course, suggest that we have here a cure for all industrial ills, that there is no

maldistribution of labour, or that all sections of a diversified area are alike benefited: there are, in fact, wide differences even between places not far apart. But he does insist that in this present age—and still more in the future—of rapidly changing technique and industrial development, it is essential to have a far better co-ordinated policy of localisation of new industries, with the twofold object of satisfying the immediate requirements of employers for labour, sites, and materials, and of building up diversified industrial areas which would be less vulnerable in times of change than our specialist centres have shown themselves to be.

It is thus seen that, in industrial areas, as in individuals, specialism may have decided disadvantages, though in both cases it is impossible to ignore the advantages of specialisation. It is, however, easier to suggest more co-ordination than to work out a practical policy to realise it. Yet the opportunities for co-ordination are greater to-day than they have ever been before. Municipal authorities in existing or potential industrial areas, transport organisations, capitalists and leaders of industry, and government representatives have now, or ought to have, wider and better knowledge of each other's needs and endeavours, and many platforms or other facilities for getting together and pushing co-ordinated effort for all it is worth.

The practical questions now are: Where, in this wide realm of ours, are there suitable areas, either of virgin type and new, or already partially industrialised, where new industries can be established? And should we consider Great Britain alone, or the whole of the British Empire? We are inclined to agree with Lord Melchett and take the Imperial view. It seems desirable, too, that agriculture should be included, for this, our greatest industry still, could be used in many ways to add variety to industrial or manufacturing life. Power, especially electrical power, is a vital factor, and therefore the electrification schemes now slowly proceeding could probably be utilised towards better co-ordination in the establishment of new industries.

A further practical help would be for a national body to determine, without unduly fettering individual freedom of choice, the selection of sites, or at least advise thereupon, rather than leave it to the discretion of municipalities and individual manufacturers. This might form part of a general policy of national development, of urban and rural planning, involving co-ordination among many different authorities.

Genetics, Mathematics, and Natural Selection.

The Genetical Theory of Natural Selection. By Dr. R. A. Fisher. Pp. xiv + 272 + 2 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1930.) 17*s.* 6*d.* net.

PROBABLY most geneticists to-day are somewhat sceptical as to the value of the mathematical treatment of their problems. With the deepest respect, and even awe, for that association of complex symbols and human genius that can bring a universe to heel, they are nevertheless content to let it stand at that, believing that in their own particular line it is, after all, plodding that does it. Although it is true that most text-books of genetics open with a chapter on biometry, closer inspection will reveal that this has little connexion with the body of the work, and that more often than not it is merely belated homage to a once fashionable study.

In the preface to his book on "The Genetical Theory of Natural Selection", Dr. Fisher deplores the cleavage between the mathematical and the biological mind, regarding it as due, not to any essential difference in intellectual make-up, but to a difference in the training of the imaginative faculty; and he brings forward an instructive example to illustrate the contrast in the two ways of approaching a problem. "No practical biologist", he writes, "interested in sexual reproduction would be led to work out the detailed consequences experienced by organisms having three or more sexes; yet what else should he do if he wishes to understand why the sexes are, in fact, always two?" To which the biologist, if acquainted with the works of the poet Hoffenstein, might be tempted to reply:

> "Breathes the man with hide so tough
> Who says two sexes aren't enough?"

In spite of Dr. Fisher's view, it is not unlikely that there may be a real genetical difference in the types of mind respectively associated with biological and mathematical thought, so that the matter-of-fact intelligence of the former will seldom be in a position to make much of a response to the imaginative flights of the latter. Nevertheless, it is at times worth the biologist's while to make a special effort, and the present volume offers an occasion; for although Dr. Fisher's mind is essentially a mathematical one, he has marked biological sympathies, and has evidently striven hard to make himself comprehensible to those without the mathematical *flair*. From his book the geneticist will get an idea of the way in which some of his problems are

viewed by a detached intelligence; but it ranges over so wide a stretch that it is impossible in a brief review to touch upon more than a few points which seem of special interest to the geneticist, for whose conversion it would appear in some measure to have been written.

That Dr. Fisher's outlook is based upon the assumption of particulate inheritance is only to be expected. Nevertheless, unlike the average geneticist, he does not reject the possibility of blended inheritance as incompatible with the vast corpus of genetical data, but on the ground that to account for such variance as is known to occur, it would demand a mutation rate some thousand-fold greater than does the particulate theory—a rate far greater than we have any grounds for supposing to exist. Yet, although founding his philosophy upon particulate inheritance, he is inclined to deny to mutations any importance in determining the direction of evolutionary change. Moreover, on the analogy of certain experiments dealing with the sensory appreciation of weights, the selective value of the mutation is regarded as in arithmetic proportion to its size, a view to which we fancy few biologists will be willing to subscribe.

Throughout the book one gets the impression that Dr. Fisher views the evolutionary process as a very gradual, almost impalpable one, in spite of the discontinuous basis upon which it works. Perhaps this is because he regards a given population as an entity with its own peculiar properties as such, whereas for the geneticist it is a collection of individuals.

It is a pity that Dr. Fisher, in formulating his views, should not have considered the group of cases of melanistic moths, one of the few in which we have clear evidence of the supplanting of one form by another within a brief period of time. Surely in such cases the mutation can be said to have determined the *direction* of evolutionary change. The marked and unequivocal dominant, as in the case of the successful melanic mutant, is an evident stumbling-block in the way of Dr. Fisher's attempt to reconcile a particulate basis with a continuous process of evolutionary change, and he has considered the matter at some length in a chapter on the evolution of dominance. His explanation in its abstract form is not easy to follow, but fortunately he has illustrated it by the concrete case of the fowl, the domesticated breeds of which are unusual in presenting a number of characteristics dominant to the corresponding ones in the reputed wild progenitor, *Gallus bankira*. Believing that the slightest differences have some selective value, Dr. Fisher sees in the wild type the form of the species most fitted to the environment, and he regards dominance as " a characteristic proper, not to the predecessor as opposed to the successor in a series of mutational changes, but to the prevalent wild type as opposed to its unsuccessful competitors ". Further, he lays down that " the rule which gives genetical dominance to genes of the prevalent wild type requires that the successful new gene should in some way *become* dominant to its competitors ".

Elsewhere Dr. Fisher states that there is no reason for supposing that the mutational process differs under natural conditions from that occurring in the laboratory or the breeding pen. Hence we must suppose that the mutational changes which give rise to dominant characteristics in domestic poultry show little or no influence in the wild form, that is, are either recessive or nearly so. On the accepted basis of particulate inheritance we must suppose that the dominant manifestation of the mutation in one case, and its relative recessivity in the other, are due to a difference in the substratum on which it acts, that is, to a different collection of modifiers in the two cases. Have we grounds, then, for supposing that this substratum differs markedly in the domesticated and in the wild; and if so, in what way has the change been brought about? Dr. Fisher suggests that it is due to the peculiar manner in which the fowl has undergone domestication.

It is known that domesticated hens may attract the wild cock and produce fertile offspring from them, and Dr. Fisher considers that at one time the fowl was kept only by jungle tribes, and that the domestic flocks were continually liable to be sired by wild birds. Hens showing some slight difference from the normal, for example, incipient crest, would be likely to be preserved through man's love of novelty. Moreover, owing to the fact that the wild bird was always the sire, these differences could not be of the nature of ordinary recessives. The mutant gene for crest must be regarded as having been brought in by the wild cock, in which it behaved as recessive to its uncrested allelomorph. But owing to a difference in the collection of modifiers in the semi-domesticated hens, it was able to gain some expression. By continually selecting for breeding those hens in which it was most markedly expressed, man was really building up a collection of modifiers which allowed of more and more marked expression, until finally the crested gene was placed on a substratum where its effect was one of unequivocal dominance.

The process should, of course, be reversible, and the transference of the crested gene to what is in

other respects a wild *bankira* should result in its becoming a virtual recessive. Dr. Fisher states that experiments on these lines are in progress, and we shall look forward with interest, and some scepticism, to the result. Meanwhile, one need not lose sight of the view that some at any rate of the dominants found in domestic fowls are due to their having had a polyphyletic origin from more wild species of *Gallus* than one. Of the four species known, three have already been shown to give fertile offspring with one another and with domestic races.

Dr. Fisher devotes a chapter to mimicry, rightly perceiving that this is crucial material for the evaluation of any theory of natural selection or of evolution. Denying, as he does, that the mutation or sport can affect the direction of evolutionary change, and being in sympathy with the stock view that natural selection can gradually bring about a condition of adaptation, Dr. Fisher is naturally brought up against Marshall's argument that Müllerian mimicry must be regarded as a special case of Batesian mimicry in that the more numerous species must dictate the nature of the warning pattern. He strives hard, we think unsuccessfully, to get round it; for in doing so he has to postulate an intermediate state enjoying the advantages of both, a very doubtful supposition even allowing that the intermediate state were itself a genetical possibility. But although he seems rather uncomfortable about the way he disposes of Marshall, stating that we "can neither assert that the Müllerian principle will work, nor that it will fail", he nevertheless bases further argument on the assumption that Marshall is wrong. We think that the facts connected with mimicry will repay closer scrutiny on Dr. Fisher's part, for nowhere does there seem to be more cogent evidence for the influence of the discontinuous in evolutionary change.

A considerable proportion of Dr. Fisher's book is devoted to considerations on the evolution of man in his social aspects. He discusses such topics as the decay of civilisations, the mental and moral qualities determining reproduction, the biological aspects of class distinction, the inheritance of fertility, and the decay of ruling classes. He points out that among barbarians the social structure is, as a rule, such that the eminent tend to be the most fertile; whereas in civilised communities social promotion is generally accompanied by infertility. The moral is clear, but the argument is presented in a manner sufficiently detached to avoid that semblance of preaching which is often so boring in works on eugenical reform. Most readers will probably find this the brightest part of the book, for, apart from the absence of mathematical formulæ, it is full of shrewd comments and odd bits of learning. Especially entertaining is the comparison between insect and human communities.

In conclusion, we cannot refrain from a few criticisms of another kind. Dr. Fisher states in his preface that "no efforts of mine could avail to make the book easy reading". That we can well believe. Nevertheless, we feel that he might well have made it much easier reading. The sentences are often unnecessarily long and tortuous, and too often, to make use of a Wellsian phrase, "overlaid with worm-casts of parentheses". Too often the effect of laboriously parsing the sentence in order to grasp its meaning detracts from the necessary effort of comprehension, and the reader feels a just irritation with a writer who might so easily have put it more clearly. As an example, we may give the sentence beginning on line 32 of p. 66, where the word 'to' occurs seven times in various relations. And what are we to make of this other sentence on the same page ?—"To postulate equal functional importance of the two homologous genes is therefore not to deny the possibility of all appearance of dominance, but that a general intermediacy of character, such as that to which attention has already been called in heterozygotes between different mutants of the same gene, should be the prevalent condition." This obscurity of diction is the more to be regretted since Dr. Fisher has given us a provocative and stimulating book, and we are left with the feeling that we might have got more out of it if only the style had been terser and more crisp.

R. C. PUNNETT.

Size and Form.

Size and Form in Plants: with Special Reference to the Primary Conducting Tracts. By Prof. F. O. Bower. Pp. xiv + 232. (London: Macmillan and Co., Ltd., 1930). 12*s*. 6*d*. net.

THE physiological exchange which is inseparable from active life is conducted through limiting surfaces, external or internal. Provided the form remains unchanged, the bulk of a growing cell, tissue, or organ increases as the cube of the linear dimensions, the surface only as the square. Accordingly, as growth proceeds, the proportion of surface to bulk decreases, until a point of physiological inefficiency is approached. The simple cell solves the problem by division, producing new surfaces along the line of cleavage, but an equally effective solution is provided by appropriate change

of form, the fluting or corrugation of the surface, the branching or segregation of the whole structure.

Prof. Bower has emphasised these facts, and has applied them not only to the external surface but also to two other surfaces of physiological transit, the endodermal sheath, where the vascular tracts abut on the surrounding tissue, and the collective surface, where the dead, water-conducting elements of the wood are in contact with living cells. He has the advantage of an unrivalled knowledge of the simplest vascular plants, the ferns and their allies, where the relation of size and form can be studied without the complication of secondary growth. In flowering plants the mass of secondary wood is broken up, interspersed with living cells and traversed by intercellular spaces, so that, in respect of the contact of dead wood elements with living tissue, the needs of increasing size are met without change of outline.

In the sporeling stages of the group of ferns and fern allies, and in the adult stems of its primitive members, the wood elements form a solid column in contact with living cells only on its external surface and lacking intercellular spaces for ventilation. It is here that Prof. Bower has been able to show, by series after series of outline figures, the close association of increasing complexity and increasing size. In the past the relation has often been obscured by the haphazard use of scales of magnification, the enlargement chosen being that which gave a convenient figure, so that the eye was misled. Here, on the contrary, the same magnification is employed throughout a series, and proper emphasis is thereby given to the striking change in size which accompanies development.

In *Psilotum* the young rhizome shows a simple, solid core of wood; as its size increases its outline becomes more elaborate, and it is finally disintegrated into strands surrounding a pith. In a club moss the wood of the sporeling is cruciform as seen in transverse section, in larger axes it is stellate and at last broken into more than twenty radiating strands; in the Cœnopterid group of fossil ferns the surface of the conducting cylinder becomes corrugated and the central cells fail to undergo lignification, forming a columnar pith. In higher ferns the pith is a permanent feature, and great elaboration in the arrangement of the wood is to be found. The endodermal sheath undergoes a similar but less striking series of changes in form, often, as in roots, preserving a circular contour when the outline of the wood is fluted and stellate in section.

Passing to seed plants, Prof. Bower draws an instructive comparison between the wood of the fossil *Sutcliffia* and the larger vascular column of the palms. In *Sutcliffia* the main conducting strand is a continuous mass of wood elements mixed with living cells; it lacks air passages; it is surrounded by similar but smaller strands. Here the contact of wood elements with living tissue is achieved, but the limit of size for an unventilated structure seems to have been reached, and the subdivision of the conducting tissue provides surface through which gaseous exchange can occur. In the well-ventilated vascular column of the palms considerably greater size is attained.

The importance of the relation between size and form is, however, by no means limited to the conducting tissues of vascular plants. Prof. Bower brings under contribution the chloroplasts of the green algæ, showing that these are relatively simple in the smaller species, ridged or flanged in their larger allies; he directs attention to the work of Prof. Hesse on the correlation between the size of the body and the absorptive surface of the gut in the lower Metazoa, and he refers to a number of other zoological examples of the importance of the size-factor in development.

In this book a point of view is elaborated which should both clarify past work and serve to stimulate research. H. C. I. G.-V.

(2) *Die gravimetrischen Verfahren der angewandten Geophysik.* Von Dr. Hans Haalck. (Sammlung geophysikalischer Schriften, herausgegeben von Prof. Dr. Carl Mainka, Nr. 10.) Pp. viii+205. (Berlin: Gebrüder Borntraeger, 1929.) 16·80 gold marks.

GEOPHYSICS, like her august sister astronomy, is experiencing a new golden age of activity and rapid advance, and in consequence a spate of geophysical books issues from the Press. As with astronomy also, the mode of publication of geo-

physical work renders the production of works of synthesis and compilation particularly desirable: whereas the researches of physicists and chemists, for example, appear almost exclusively in regular scientific periodicals, which are purchasable through any bookseller, much of the work of astronomers and geophysicists, both on the observational and theoretical sides, appears in the publications of observatories and expeditions, which are often not readily available to private workers, are issued at irregular intervals, and in many cases are not referred to in *Science Abstracts* and similar journals.

The three German books under review are to be welcomed as useful additions to geophysical literature, even where, as in the one dealing with terrestrial magnetism and polar lights, other books on the same subject have recently appeared. While in such cases there is considerable common ground in the different treatments, the divergent interests of different authors, in such wide fields of study, lead to the inclusion by one author of material not mentioned, or only slightly emphasised, by another; the additional facts, views, and references thus made readily available justify the purchase and perusal of the several overlapping works.

(1) Two of the volumes are part of a large collective "Introduction to Geophysics". In the work by Prof. Defant on dynamical oceanography, his aim has been to describe the motion of water in the seas and oceans in the light of the underlying dynamical and physical principles: and in so doing some gaps in the theory have been newly filled in. The part of the subject dealing with waves and tides is treated only briefly, as there is already a considerable literature specially devoted to it. The main theme is the great oceanic circulations and currents, the forces which give rise to them, and the modifications due to the rotation of the earth and the friction and conformation of the oceanic beds and boundaries. The author has given an excellent brief general account of the subject, incorporating much recent work and, by diagrams and otherwise, bringing into close relation with one another the observed facts and the results of research on associated idealised problems. The index of writers quoted in the book illustrates well the author's prefatory remark that, as yet, German workers in oceanography have been few; English, American, and Scandinavian names largely predominate.

In Prof. Nippoldt's admirable brief summary of terrestrial magnetism and polar lights, the space given to the main sections of the subject is as follows: instruments and measurements, 46 pages; the main magnetic field and its secular variation, 63 pages; the transient variations (daily and irregular), 39 pages; and auroræ, 21 pages. In view of the fact that the author is a leading authority on the magnetic distribution and anomalies over Europe, it is natural, and welcome, that this subject is particularly well illustrated and described. The treatment also of other aspects of the subject is clear, concise, and attractive; the diagrams are numerous and well chosen, and the critical accounts of theoretical work, though very brief, are (with few exceptions) excellent.

Prof. Schweidler's interesting summary of atmospheric electricity occupies 91 pages; it will give the non-specialist reader a good general knowledge of the leading problems and results in this field, apart from questions of instruments or measurements, which are not discussed. It is concerned almost entirely with the lower atmosphere, and the Heaviside layer, with its relations to radio transmission and terrestrial magnetism, is not considered.

Dr. Keranen's contribution comprises 122 pages; it relates to a subject which, so far as we know, has not hitherto been summarised in this way. It deals with the intake and emission of heat at and just below the earth's surface, assuming the sun to be the sole source of the heat-changes. The mathematical theory of the subject, so far as it has yet been developed (including that of the downward penetration of periodic temperature variations by thermal conduction), is briefly reproduced. Methods of observation, and the influence of different surface coverings (such as vegetation or snow) on the temperature variations, are carefully considered, and a chapter is devoted to ground frost and its penetration below the surface. Dr. Keränen's account should prove of interest and value to engineers as well as to those concerned mainly with pure science.

(2) The third volume is specially addressed to those wishing to use geophysical science for immediately practical ends. After a brief account of the theory of the gravitational potential (24 pages), and of pendulum observations for the measurement of the direction and intensity of gravity (31 pages), the author proceeds to his main themes; these are the measurement of intensity gradients and of the curvatures of the equipotential surfaces, by means of the Eotvös balance in its various forms (52 pages), the reduction of these measurements (56 pages), and their physico-geological interpretation (38 pages). The volume is a valuable companion to the same author's book on magnetic methods in applied geophysics.

Our Bookshelf.

The Art of Retouching Photographic Negatives: and Practical Directions how to finish and colour Photographic Enlargements, etc. By Robert Johnson. Twelfth edition, revised and rewritten by T. S. Bruce and Alfred Braithwaite. Revised and enlarged by Arthur Hammond. Pp. x+154+16 plates. (London: Chapman and Hall, Ltd., 1930.) 12*s*. 6*d*. net.

That a twelfth edition of Robert Johnson's handbook on the art of retouching has been published is testimony to its excellence and to the fact that progress is constantly being made in the methods and appliances for working up and finishing photographs. The leading professional photographers of the world have so developed their art and their lighting systems that their finished results owe but little to the skill of the retoucher, and their clients are learning to accept the straightforward untouched portrait as a better thing than the old over-retouched ones that former generations demanded. There is, however, still a great majority that demands that their likenesses shall be smoothed out of all semblance of their natural selves, whilst the technical equipment of many photographers is unequal to providing what is required without extensive use of the retoucher's skill. There is also a legitimate demand for skilled retouching in commercial and industrial photography. For these purposes this handbook gives full but concise instructions in the difficult art, but, as the writers confess, success depends rather upon intelligent practice than upon following any printed directions. It is mainly a matter of manual skill wisely directed.

The latest revision of the book is by Arthur Hammond, an associate of the Royal Photographic Society. A comprehensive and painstaking account is given of the materials and methods to be used, of the modelling of each feature of the face, of the working up of backgrounds, etc., of the retouching of landscape, architecture, and animals with pencil, brush, and airbrush. Finally, a series of chapters is devoted to the colouring of photographs by all suitable methods. The whole forms a complete text-book of the retoucher's art based on modern practice. J. Dudley Johnston.

Sexual Life in Ancient India: a Study in the Comparative History of Indian Culture. By Johann Jakob Meyer. (The Broadway Oriental Library.) Vol. 1. Pp. xi+275. Vol. 2. Pp. ix+277-591. (London: George Routledge and Sons, Ltd., 1930.) 36*s*. net.

The "Broadway Oriental Library", of which this work is one of the initial issue, will meet a very real need if it follows the line suggested in the general introduction. It is primarily intended for those who are interested generally in the results of Oriental studies rather than in their technical and highly specialised details. Oriental studies are at present not well served in this respect, especially as regards India. Much material of the highest value to the student of culture is rendered difficult of access because of the form in which it is cast.

"Sexual Life in India" is an attempt to give an account of the life of women in ancient India based upon the two great epics, the Mahabharata and the Ramayana. It covers the religious and social, as well as the sexual, sides of that life. From this material the author has extracted the most intimate details as to the relation of the sexes. The importance of such matters in the life of the East, and particularly of India, is difficult to overestimate. It gives an orientation to the mind of the East which the West finds difficult to grasp. Prof. Meyer's study is comprehensive within limitations: it deals with the position of the daughter in the family; preparation for marriage; the duties and position of the wife; motherhood; the widow; sexual relations, both regular and irregular, and so forth. But it does not tell the whole story. The material is necessarily, in view of its source, somewhat idealised, and certain sides of sexual life do not come within its purview. This, however, does not detract from the value of the book as a social document. It depicts the theory, if not in all respects the practice, of a certain section of Indian society. For the purposes of this translation, the author has revised the text and added to the notes, to which one of the translators has made further additions.

The Zeta-Function of Riemann. By Prof. E. C. Titchmarsh. (Cambridge Tracts in Mathematics and Mathematical Physics, No. 26.) Pp. vi+104. (Cambridge: At the University Press, 1930.) 6*s*. 6*d*. net.

The function now known as Riemann's zeta-function may be defined as the sum of the s^{th} powers of the reciprocals of all the positive integers from unity to infinity. This definition only holds for a certain range of values of s, but it may be generalised, in the usual way, by contour integration. So far back as 1737, Euler had noticed the relation between this function and an infinite product involving primes. No further progress seems to have been made until 1859, when Riemann, in a short paper of only ten pages, indicated a number of ideas which have proved extraordinarily fruitful, and from which many modern researches have developed.

It will surprise those who look upon mathematics as a cut-and-dried science, leaving no scope for imagination and intuition, that an important part of Riemann's work consisted in six theorems which he believed to be true but could not prove. Hadamard at last succeeded with three of these in 1893, while von Mangoldt dealt with two others in 1895 and 1905. The sixth, the famous hypothesis that all the complex zeros have a real part $\frac{1}{2}$, is still unproved.

Prof. Titchmarsh's tract is chiefly devoted to researches produced since Landau's extensive work (1909), but he gives also a brief sketch of earlier work. Some use has been made of an unpublished manuscript by Profs. Littlewood and H. Bohr. The application to the theory of numbers is being dealt with in a companion volume by Mr. A. E. Ingham. H. T. H. P.

The Stomatic Control of Transpiration.

THE magnitude of the influence exercised by the stomata in the regulation of the water losses of plants appears to be very different under different conditions.

It has been found that when the mesophyll is rich in water the water loss is largely independent of the stomatic area ('aperture', measured by the porometer) if other conditions are constant.

When a widely open stoma changes in size, the margin of its opening scarcely alters in length. The change in area is due almost entirely to alteration of the length of the short axis.

The following experiment demonstrates that the rate of diffusion of vapour from slit-like apertures is independent of the breadth of the slit (in the case of moderately narrow slits) and is dependent in the main on the length of the slit or of its margin only.

Glass cover slips were cemented over the open ends of a number of cylindrical specimen-tubes leaving approximately rectangular openings, of which the lengths equalled the diameters of the tubes. These tubes were filled with petrol and weighed. The petrol was allowed to evaporate into the air, which may be regarded as a perfect sink for petrol vapour. After ten hours' evaporation the tubes were weighed again; the losses in weight of the various tubes and the dimensions of the slits through which the evaporation took place are recorded in the table below. The first eight experiments made are shown.

Expt.	Length in mm.	Width in mm.	Rel. wt. evptd.	Rel. margin.	Rel. area.
1	11·5	0·16	100	100	100
2	10·5	0·90	97	98	514
3	11·0	1·44	103	107	862
4	11·0	1·40	116	106	838
5	10·9	3·20	100	121	1897
6	7·1	1·18	60	71	452
7	18·3	1·20	252	167	1193
8	23·0	1·15	352	207	1437

From these results it is clear that the breadth of a narrow rectangular opening does not sensibly affect the amount of diffusion through it: in other words, the rate of diffusion through narrow openings is proportional, not to the areas, but to the lengths of the margins of the openings.

It has been pointed out elsewhere ("Transpiration and the Ascent of Sap", p. 5) that the results of Brown and Escombe may be stated in this manner. However, their observation that the amount of vapour transmitted by diffusion through a circular aperture is proportional to its radius does not account for the fact that, while the closing of widely open stomata is not accompanied by a reduction in transpiration, the final stages of the closing bring about a marked falling off in water loss.

This result is, however, inevitable when we consider that owing to the form of the stomata, during the earlier stages of the closing the margin remains the same length, while, during the final stages, the length of the slit, and consequently that of the margin, is rapidly decreased.

Oviposition of *Hæmatopota pluvialis* Linné.

THE association of tabanid species with their eggs has been determined in only a comparatively few cases. Despite the local abundance of Tabanidæ in tropical, sub-tropical, and temperate countries, the egg-masses and egg-laying habits of many of our common species have consistently escaped the observation of investigators. Not only has the discovery of the eggs in Nature proved elusive, but also frequently the attempts to induce oviposition under controlled conditions in the laboratory have been attended with little or no success. Consequently the biology of many species that have been studied is incomplete. The reasons for this hiatus in our knowledge I have already discussed in a previous paper ("Tabanidæ of the Canadian Prairie", *Bull. Entom. Res.*, **17**; 1926). Failure to find eggs has led investigators at various times to suggest that some species may deposit their eggs indiscriminately in the soil instead of ovipositing on the leaves and stems of semi-aquatic plants or on the surfaces of stones in or near water. This hypothesis would appear to be supported by the occasional finding of tabanid larvæ in comparatively dry soil at some distance from water. In western Canada *Tabanus Reinwardtii* Wied. and *Chrysops fulvaster* O.S. are common species, the eggs of which were not found although diligently sought in localities where these species were abundant. It was surmised that the eggs might be laid separately in the soil and thus render their discovery difficult. Both of these species were, however, induced to oviposit in glass jars in the laboratory, when they produced masses similar in all respects to those that are normally laid on leaves by other members of the family.

A survey of the literature of European Tabanidæ shows that the eggs of only two species are known. In 1854 Kollar found the eggs of *Tabanus quattuornotatus* Meig. ("Beitrag zum Haushalten der sehr lästigen Viehbremsen (Tabanidæ)", *Sitzungsber. d. Akad. d. Wiss.*, Wien, 13), and they were again observed and described by Lécaillon in 1905 ("Sur la ponte des œufs et la vie larvaire des Tabanides, particulièrement du Taon à quatre tâches (*Tabanus quattuornotatus* Meig.)", *Ann. Soc. entom. France*). Two further contributions on the eggs of this species were made by the same author in 1906 (*Compt. rend. Soc. Biol.*, 60) and 1911 (*Ann. Soc. entom. France*, 80). In 1909 Surcouf and Ricardo ("Étude monographique des Tabanides d'Afrique", Paris) recorded the discovery of the eggs of *T. autumnalis* L. at Lamballe (Côtes-du-Nord) in 1907. Unfortunately, the eggs were not collected when first seen, and on the following day, when a return visit was made, the grass on which the eggs had been deposited was found to have been mown.

Up to the present there is no record of the finding of the eggs of any species of *Hæmatopota*. This is remarkable considering the relative abundance and wide distribution of the genus, of which *H. pluvialis* is our commonest species. In Scotland it is locally very abundant from June to September, and can be readily collected in rural districts where there are ponds and bogs. During July of this year specimens were collected at Threipmuir reservoir, Balerno, near Edinburgh, and were permitted to feed either on the hand and forearm of a human host or on the ear of a rabbit. Some fed immediately the host was presented, and became engorged in ten minutes or less. Others refused to feed after repeated trials from day to day. A female that has partaken of a full blood-meal in the laboratory does not feed a second time, and it is surmised that those specimens which refuse to feed in the laboratory at the first and subsequent trials may have already fed in Nature before they were captured.

Of those that were induced to feed, one deposited a mass of 75 eggs on the walls of a glass jar, in which it was confined, 10 days after engorgement. A layer of moist sand was placed in the bottom of the jar, and into the sand there were stuck the stems and leaves of grasses in an upright position. The escape of the fly was prevented by plugging the mouth with a wad of cotton-wool. In this way the atmosphere in the jar was maintained fresh and slightly humid, and the flies continued to live for two to three weeks. A second fly kept under these same conditions deposited a mass of 125 eggs on the flowering head of perennial rye-grass inside the jar. The accompanying photograph (Fig. 1) shows this second egg-mass. Both

FIG. 1.—Eggs of *Hæmatopota pluvialis* L. on flower of *Lolium perenne*. ×8.

batches of eggs were fertile. Mating probably occurs soon after the adults emerge from the pupæ. In this regard it is interesting to note that a swarm composed entirely of males was observed on the bank of Thriepmuir reservoir on July 19 at 11 A.M. It maintained a position just out of arm's-reach above a chironomid swarm.

The process of egg-laying was carefully observed. The ovipositing behaviour of the fly conforms exactly to that of other tabanid species in which it has been observed (Cameron, loc. cit., 1926). The head of the female is directed downwards, and the abdomen recurved ventrally and anteriorly in the actual laying of the individual eggs. In the interval between the laying of one egg and another, the ovipositor is withdrawn and the abdomen straightened. Each egg, as it is laid, receives a thin coating of cement, which is brushed on by the tip of the ovipositor. This cement is a secretory product of the enlarged, accessory, vaginal glands. The eggs are laid almost vertically to the surface chosen for oviposition, and they remain firmly attached to this and to each other. Having completed one layer the fly proceeds to deposit a second on top of the first. The eggs of this superimposed layer adhere to those of the first end to end. The time occupied in the deposition of the individual eggs averages 15 seconds. They are at first white, but gradually darken to a greyish brown. The egg is cylindrical, tapering slightly to the rounded ends. The average length is 1·612 mm., and the average breadth is 0·29 mm. Hatching occurred in about 10 days under mean daily laboratory temperatures of 60° F. The first instar possesses a prominent, black, sharp-edged, labral, hatching spine, and emerges through a slit, which extends posteriorly for one-third the length of the egg on the antero-dorsal side of the chorion. The cephalic capsule is rudimentary with weak mouth-parts, and is in direct contrast to that of the second-stage larva, which is well developed and resembles in all respects the cephalic capsule of the full-grown larva. The first instar does not feed, but subsists on the occluded yellowish yolk-mass in the mid-gut. Soon after hatching, the first-instar larva moults, and the second instar commences to feed. In the absence of suitable food the second instar will continue to subsist on the remainder of the occluded yolk-mass, and will live unimpaired for four or five days, if kept in a moist atmosphere, without partaking of extraneous food.

A female *H. pluvialis* captured on Aug. 7 fed on a rabbit the same day. This specimen lived in the laboratory for 17 days without ovipositing, when it died. Dissection showed that the ovaries were mature, each containing about 50 eggs.

The investigation of the biology of *H. pluvialis* is to be continued and extended.

Velocity of Sound in Tubes: Ultra-Sonic Method.

THERE are points still uncertain concerning the velocity of sound in fluids contained in tubes. Relatively little experimental work has been carried out in liquids as the contained fluid, but outstanding is the research of Dorsing (*Ann. der Physik*, **25**, pp. 227-251; 1908), who reported certain cases of *increase* of the velocity as compared with the velocity in the same liquid when unconfined. Generally there is expected a decrease in velocity depending on the diameter of the tube. Unlike most experimenters, Dorsing employed a relatively high frequency in his experiments, about 4000 vibrations per second; so also did Busse (*Ann. der Physik* (4), **75**, pp. 657-664; 1924), who adopted Dorsing's method to determine some useful thermodynamical constants.

Considering the elasticity of the tube wall, corrections to the velocity should be applied for the waste of energy laterally by the vibrations of the wall. No wall is *rigid* to any elastic vibrations, and, in consequence, the wall vibrations (of any type) will cause a damping of the longitudinal vibrations in the contained fluid column. This damping causes a diminution of longitudinal velocity in the column, but generally the diminution is small. The phenomenon has been observed experimentally, and also investigated mathematically, most recently by Gronwall (*Phys. Rev.*, **30**, pp. 71-83; 1927). Pooler (*Phys. Rev.*, **31**, pp. 157-158; 1928) has found an experimental verification of Gronwall's relation by determining experimentally the velocities in a column of liquid contained in a vertical cylindrical steel tube. The vibrations used were of audio frequency, generated by an electromagnetically excited diaphragm at the bottom of the column.

When present-day ultra-sonic methods are applied to the further elucidation of this problem, new and interesting results are disclosed. By using ultra-

sonic frequencies, wave-lengths can be employed comparable to the diameter of the column; it turns out that it is then possible to cause at will largely augmented, as well as largely diminished, phase velocities in the liquid of the column—in fact, the velocity-frequency curve is like the selective absorption curve of optics. An actual curve obtained by employing quartz-metal ultra-sonic generators in a glass tube 3·5 cm. in diameter, 57·3 cm. long, wall thickness 2 mm., with naphtha as the contained fluid, is shown in Fig. 1. The frequencies here employed ranged from 25,000 to 74,000 cycles per second, the 'absorption band' appearing between frequencies 34,000 and 40,000 cycles per second. Phase velocities ranged from 0·9 to 2·1 × 10^5 cm. per sec., the undisturbed velocity being 1·35 × 10^5 cm. per second.

The experimental method employed was that of stationary waves, the best adaptation so far being an arrangement whereby the positions of the stationary waves could be *seen* by the eye and their breaking up in the frequency range of the absorption band observed visually. Consequently, tubes of transparent materials like celluloid and glass were used, with clear liquids like water, naphtha, chloroform, and oil. Moreover, by taking advantage of the phenomenon of ultra-sonic cavitation, bubbles of gas produced in the liquid by the ultra-sonic vibrations could be made to locate in curtains marking the positions of the nodes of the stationary waves. From the positions of these curtains the measurements of wave-length were taken, from which velocities were computed. It is extremely difficult to get good stationary waves to form, and so permit good determinations of velocity, in the region of frequencies covered by the absorption band.

The best method of generating the stationary waves consisted in the use of two quartz oscillators instead of one, an oscillator being placed at each end of the experimental tube (Fig. 2). These oscillators were made as nearly as possible identical, and were connected in parallel to the oscillating electrical circuit, so that the same frequency and voltage were imposed on each. The positions of the oscillator in the tube were capable of slight adjustment so that the best stationary wave formation could be obtained. But no matter what the method of experiment or what tubes or experimental liquids used, the velocity-frequency curve always had a form like Fig. 1. The same type of experiment carried out at the same frequencies in columns of air only gave the usually anticipated velocity, but no special search for absorption bands was made in this case.

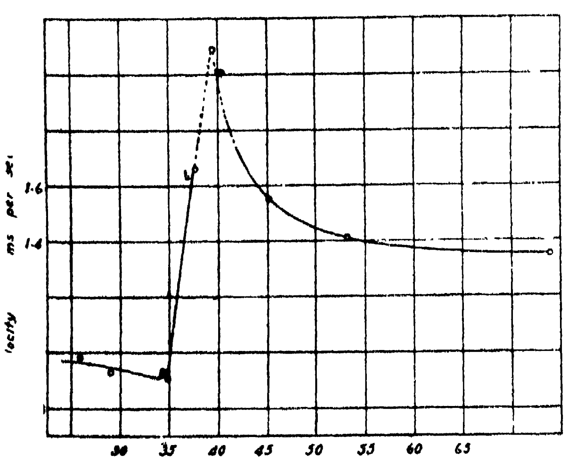

FIG. 1.

All the results obtained on liquids have not yet been analysed, so that it is not yet known with certainty what is the particular form of energy transference which causes this phenomenon; the experiments were of necessity interrupted more than a year ago and are now being resumed.

Splitting of the Frequency of Light scattered by Liquids and Optical Anisotropy of Molecules.

As has already been reported (see NATURE, Aug. 9, 1930), the frequency of light scattered by liquids or crystals is split into several components, and their position in the case of strongly scattering liquids like benzene and toluene may be represented by the expression

$$\left(1 \pm 2n \frac{v}{c} \sin\frac{\theta}{2}\right), \text{ where } n = 0, 1, 2, 3.$$

The study of the polarisation of different components of light scattered by benzene has shown that the central unmodified line and two neighbouring ones, the 'inner' components ($n = 0$ and $n = 1$), are strongly polarised, the electric vector being perpendicular to the direction of incident light. On the contrary, the other, 'outer' components ($n = 2, 3$) are not polarised. Thus the depolarisation of the light scattered by liquids is connected with the presence of the 'outer' unpolarised components. It may, therefore, be supposed that in liquids with large coefficients of depolarisation (strongly scattering liquids) the intensity of 'outer' components is relatively greater than in liquids with small depolarisation (weakly scattering liquids).

In fact, further experiments with carbon disulphide, which possesses optical anisotropy to a high degree, have shown that for this substance 'outer' components are very intensive, being almost of the same intensity as the 'inner' ones. The same may be said of chlorbenzene. On the other hand, for water, ethyl ether, and alcohol, which have very small optical anisotropy, I could not establish with certainty the existence of 'outer' components. Probably they are very weak, and the satellites of the hyperfine structure of the mercury-line (λ4358 A.) prevent their detection.

It may be concluded from these experiments that the existence of 'outer' components is associated with the depolarisation, and the liquids which do not produce depolarisation have not such components.

It may be supposed that the appearance of 'outer' components is due to the diffraction of light, by 'heat-wave lattices' of harmonics, that is, they are produced

by lattices with a constant smaller than the half of the wave-length of incident light. In the domain of X-rays such reflections are, as is well known, impossible. It may be that in the case of scattering of light, owing to the depolarisation, they become possible.

These experiments (with echelon grating) corroborate the view expressed in my previous communication [see NATURE, **126**, p. 400; Sept. 13, 1930] that the broadening (nebulosity) of original lines of the mercury arc after scattering in some liquids (of the order 40-50 A.), which can be observed with spectrographs of small resolving power, is probably connected with the existence of 'outer' components (with $n > 3$). The stronger the depolarisation of the light scattered by the liquid, the stronger must be the 'outer' components, and more pronounced broadening of original lines will result. This is in accordance with the observations of Raman and Krishnan (NATURE, **122**, p. 882; 1928), and my own unpublished experiments with a spectrograph of moderate dispersion that this broadening of scattered lines is connected with the optical anisotropy of the molecules of the liquid.

If the above explanation is correct, the broadened lines must have a definite boundary the position of which corresponds to the greatest possible frequency $\nu_{max.}$ of the Debye 'acoustic spectrum', and therefore must depend for various liquids upon the velocity of sound and the distance between molecules. Experiments now in progress seem to support this view.

Leningrad, Sept. 8.

Energies of the C – I and C – Br Bonds.

THE absorption spectra of methyl, ethyl, and isoamyl iodides consist, in the near ultra-violet, of broad continuous bands, with maxima at about 2550 A., and at high vapour pressures, a fairly well defined long wave-length limit at 3340 A. Undoubtedly this corresponds to dissociation into an excited iodine atom and an alkyl residue, and the process might be considered analogous to the disruption of hydriodic acid, HI. If we accept Mecke's figure (NATURE, April 5, 1930) for the energy of the C – H bond (115 kcal.) in hydrocarbons, there is very nice agreement between the thermochemical and spectroscopic data for the energy of the C – I bond. Using Berthelot's figures for the heats of combustion of the alkyl iodides, this energy is calculated to be 65 kcal. Allowing for the excitation energy of the I atom (21 kcal.), the spectroscopic figure is 64 kcal.

With ethyl bromide, assuming that the dissociation is of a similar nature, there is not such excellent agreement. The long wave-length absorption limit of C_2H_5Br appears to be 2800 A. Allowing for the excitation energy of the bromine atom (10 kcal.), the energy of the C – Br bond comes out to be 91 kcal., whereas the thermochemical value is 80 kcal. A discrepancy of the same order of magnitude has already been observed in the case of hydrobromic acid, HBr.

In the liquid state the absorption limits are found to alter, though they are no less well defined than in the gas state. If we allow for the molar heat of vaporisation and compare the minimum dissociation energies of the molecules as imagined free from each other's influences in the two states, these energies are 20 kcal. less in the liquid state for the iodides, and 10 kcal. less for ethyl bromide. It is possible that the molecule dissociates when its total energy increase (electronic, vibrational, etc.) is equal to the heat of dissociation. The absence of a rotational quantisation which is apparent with certain liquids is probably a contributing factor to the instability of the molecule on excitation. The mode of dissociation must be different in the liquid and gas states.

In a paper shortly to be published we hope to describe the experimental work from which the above data were obtained.

Zacyntha verrucosa Gärtner: Another Plant with Six Somatic Chromosomes.

AMONG many thousands of flowering plants which have been subjected to cytological investigation, there are known only two examples of a chromosome number so low as six in the diploid condition. One of them is the well-known case of *Crepis capillaris* (L.) Wall. (*C. virens* Vill.), first discovered in 1909.[1] The second reported case is *Callitriche autumnalis* L.[2]

After having studied a great many related genera and species I chanced to find an additional six-chromosome species—a distant relative of *Crepis capillaris*. This species is *Zacyntha verrucosa*. Together with *Crepis* it belongs to the chicory tribe of Compositæ—a group of plants which may now be said to be distinguished by the low chromosome numbers of its representatives.

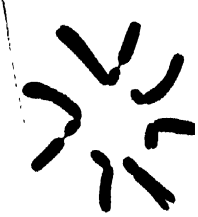

FIG. 1.—Somatic chromosome group of *Zacyntha verrucosa* Gartner. From a root tip taken from an adult plant. ×2250.

The somatic complement of *Zacyntha* is shown in Fig. 1. From this figure one can see the peculiarity of the largest pair of chromosomes, each of them bearing a large satellite on the proximal short arm. The remaining two pairs exhibit slight although distinct differences of size (especially of their smaller arms).

It is premature as yet to say whether *Zacyntha* will prove to be of genetic interest comparable to that of *Crepis*, for, being a monotypic genus, it may fail to cross with any other species. Investigation is in progress now, and additional data on this new object as well as a full account of its cytology will be published elsewhere in the near future.

M. NAVASHIN.

English Equivalents of *Eigenfunktion* and *Eigenwert*.

IN publications dealing with wave mechanics there is a growing practice of rendering the words *Eigenfunktion* and *Eigenwert* into English by *eigen-function* and *eigen-value* respectively. The English expressions *proper function* and *proper value* are equally concise, correspond exactly in etymology to the originals, and have the sanction of Prof. Schrödinger himself in the English lectures which he gave at the Royal Institution. Is it not desirable, therefore, that we should discontinue the use of the mixed forms, which is a barbarism without sense or convenience, and equally repellent to German and to English ears?

The Proton.*

By Dr. P. A. M. DIRAC, F.R.S.

MATTER is made up of atoms, each consisting of a number of electrons moving round a central nucleus. It is likely that the nuclei are not simple particles, but are themselves made up of electrons, together with hydrogen nuclei, or protons as they are called, bound very strongly together. There would thus be only two kinds of simple particles out of which all matter is built, the electrons, each carrying a charge $-e$, and the protons, each carrying a charge $+e$.

It should be mentioned here that there is a difficulty in this point of view provided by the nitrogen atom. One can infer from the charge and mass of the nitrogen nucleus that it should consist of 14 protons and 7 electrons, but it appears to have properties inconsistent with its being composed of an odd number of simple particles. However, very little is really known about nuclei, and the opinion is generally held by physicists that some way of evading this difficulty will be found and that all nuclei will ultimately be shown to be made up of electrons and protons.

It has always been the dream of philosophers to have all matter built up from one fundamental kind of particle, so that it is not altogether satisfactory to have two in our theory, the electron and the proton. There are, however, reasons for believing that the electron and proton are really not independent, but are just two manifestations of one elementary kind of particle. This connexion between the electron and proton is, in fact, rather forced upon us by general considerations about the symmetry between positive and negative electric charge, which symmetry prevents us from building up a theory of the negatively charged electrons without bringing in also the positively charged protons. Let us examine how this comes about.

The energy W of a particle in free space is determined in terms of its momentum p according to relativity theory by the equation

$$W^2/c^2 - p^2 - m^2c^2 = 0,$$

where m is the rest-mass of the particle and c is the velocity of light. This equation can easily be generalised to apply to a charged particle moving in an electromagnetic field and can be used as a Hamiltonian to give the equations of motion of the particle, and thus its possible tracks in space-time.

Now the above equation is quadratic in W, allowing of both positive and negative values for W. Thus for some of the tracks in space-time the energy W will have positive values and for the others negative values. Of course a particle with negative energy (kinetic energy is referred to throughout) has no physical meaning. Such a particle would have less energy the faster it is moving and one would have to put energy into it to bring it to rest, quite contrary to anything that has ever been observed.

The usual way of getting over this difficulty is to say that the tracks for which W is negative do not correspond to anything real in Nature and are to be simply ignored. This is permissible only provided that for every track W is either always positive or always negative, so that one can tell definitely which tracks are to be ignored. This condition is fulfilled in the classical theory, where W must vary continuously, since W can never be numerically less than mc^2 and is thus precluded from changing from a positive to a negative value. In the quantum theory, however, discontinuous variations in a dynamical variable such as W are permissible, and detailed calculation shows that W certainly will make transitions from positive to negative values. We can now no longer ignore the states corresponding to a negative energy and it becomes imperative to find some physical meaning for them.

We can deal with these states mathematically, in spite of their being physically nonsense. We find that an electron with negative energy moves in an electromagnetic field in the same way as an ordinary electron with positive energy would move if its charge were reversed in sign, so as to be $+e$ instead of $-e$. This immediately suggests a connexion between negative-energy electrons and protons. One might be tempted at first sight to say that a negative-energy electron *is* a proton, but this, of course, will not do, since protons certainly do not have negative kinetic energy. We must therefore establish the connexion on a different basis.

For this purpose we must take into consideration another property of electrons, namely, the fact that they satisfy the exclusion principle of Pauli. According to this principle, it is impossible for two electrons ever to be in the same quantum state. Now the quantum theory allows only a finite number of states for an electron in a given volume (if we put a restriction on the energy), so that if only one electron can go in each state, there is room for only a finite number of electrons in the given volume. We thus get the idea of a *saturated* distribution of electrons.

Let us now make the assumption that almost all the states of negative energy for an electron are occupied, and thus the whole negative-energy domain is almost saturated with electrons. There will be a few unoccupied negative-energy states, which will be like holes in the otherwise saturated distribution. How would one of these holes appear to our observations? In the first place, to make the hole disappear, which we can do by filling it up with a negative-energy electron, we must put into it a negative amount of energy. Thus to the hole itself must be ascribed a positive energy. Again, the motion of the hole in an electromagnetic field will be the same as the motion of the electron that would fill up the hole, and this, as we have seen, is just the motion of an ordinary particle with a charge $+e$. These two facts make it reasonable to assert that *the hole is a proton.*

* Based on a paper read before Section A (Mathematical and Physical Science) of the British Association at Bristol on Sept. 8.

In this way we see the proper rôle to be played by the negative-energy states. There is an almost saturated distribution of negative-energy electrons extending over the whole of space, but owing to its uniformity and regularity it is not directly perceptible to us. Only the small departures from perfect uniformity, brought about through some of the negative-energy states being unoccupied, are perceptible, and these appear to us like particles of positive energy and positive charge and are what we call protons.

This theory of the proton involves certain difficulties, which will now be discussed. The theory postulates the existence everywhere of an infinite number of negative-energy electrons per unit volume, and thus an infinite density of electric charge. According to Maxwell's equations, this would give rise to an infinite electric field. We can easily avoid this difficulty by a re-interpretation of Maxwell's equations. A perfect vacuum is now to be considered as a region in which all the states of negative energy and none of those of positive energy are occupied. The electron distribution in such a region must be assumed to produce no field, and only the departures from this vacuum distribution can produce a field according to Maxwell's equations. Thus, in the equation for the electric field E

$$\operatorname{div} E = -4\pi\rho,$$

the electric density ρ must consist of a charge $-e$ for each state of positive energy that is occupied, together with a charge $+e$ for each state of negative energy that is unoccupied. This gives complete agreement with the usual ideas of the production of electric fields by electrons and protons.

A second difficulty is concerned with the possible transitions of an electron from a state of positive energy to one of negative energy, which transitions were the original cause of our having to give a physical meaning to the negative-energy states. These transitions are very much restricted when nearly all the negative-energy states are occupied, since an electron in a positive-energy state can then drop only into one of the unoccupied negative-energy states. Such a transition process would result in the simultaneous disappearance of an ordinary positive-energy electron and a hole, and would thus be interpreted as an electron and proton annihilating one another, their energy being emitted in the form of electromagnetic radiation.

There appears to be no reason why such processes should not actually occur somewhere in the world. They would be consistent with all the general laws of Nature, in particular with the law of conservation of electric charge. But they would have to occur only very seldom under ordinary conditions, as they have never been observed in the laboratory. The frequency of occurrence of these processes according to theory has been calculated independently by several investigators, with neglect of the interaction between the electron and proton (that is, the Coulomb force between them). The calculations give a result much too large to be true. In fact, the order of magnitude is altogether wrong. The explanation of this discrepancy is not yet known. Possibly the neglect of the interaction is not justifiable, but it is difficult to see how it could cause such a very big error.

Another unsolved difficulty, perhaps connected with the previous one, is that of the masses. The theory, when one neglects interaction, requires the electron and proton to have the same mass, while experiment shows the mass ratio to be about 1840. Perhaps when one takes interaction into account the theoretical masses will differ, but it is again difficult to see how one could get the large difference required by experiment.

An idea has recently been put forward by Oppenheimer (*Phys. Rev.*, vol. 35, p. 562) which does get over these difficulties, but only at the expense of the unitary theory of the nature of electrons and protons. Oppenheimer supposes that all, and not merely nearly all, of the states of negative energy are occupied, so that a positive-energy electron can never make a transition to a negative-energy state. There being now no holes which we can call protons, we must assume that protons are really independent particles. The proton will now itself have negative-energy states, which we must again assume to be all occupied. The independence of the electron and proton according to this view allows us to give them any masses we please, and further, there will be no mutual annihilation of electrons and protons.

At present it is too early to decide what the ultimate theory of the proton will be. One would like, if possible, to preserve the connexion between the proton and electron, in spite of the difficulties it leads to, as it accounts in a very satisfactory way for the fact that the electron and proton have charges equal in magnitude and opposite in sign. Further advances in the theory of quantum electrodynamics will have to be made before one can deal accurately with the interaction and see whether it will settle the difficulties, or whether, perhaps, a new idea can be introduced which will answer this purpose.

Physiological Effects of Work in Compressed Air.

THE average man always finds it surprising that our bodies can support such atmospheric pressures as 100 lb. per sq. in. without the slightest derangement of the delicate structures and processes on which life depends, but that, owing to a secondary effect, the return to normal pressure is accompanied by grave risk. A sojourner in compressed air inevitably soaks up a considerable volume of the nitrogen of the air into simple solution in the tissues and fluids of his body. So long as the pressure is maintained this gas remains hidden and harmless, but any reduction of pressure will drive it out of solution. The critical time in the management of compressed air workers is the period of decompression when they are passing from high air pressures down to the normal. Given time, the blood will carry off the excess gas and discharge it to the atmosphere in the lungs as the

pressure falls, but a rapid decompression overloads the blood with excess gas, which bursts out in the form of bubbles and chokes the circulation with froth.

Compressed air is used by engineers to keep back water in sinking the foundations of bridges and in tunnelling under rivers; besides the men engaged in such work, divers using the ordinary rubber dress have to breathe air at high pressures. The joint discussion between the Sections of Engineering and Physiology of the British Association at Bristol attracted leading exponents of practice and theory in both these lines of work. Although divers are fewer in number than tunnel workers and their occupation is of less public importance, most of the recent research and experimental work has been directed to their special circumstances, and those responsible for diving work have been quick to take advantage of any new knowledge. An outstanding example is the action of the British Admiralty in being the first to adopt the entirely novel system for conducting the decompression which was devised by Prof. J. S. Haldane and has since been taken up by most of the navies of the world. Its value for divers has now been established by twenty-five years' experience, and particularly in some recent salvage operations where more than five thousand dives were made at pressures between 50 lb. and 60 lb. per sq. in. without accident.

The circumstances of tunnel workers differ from those of divers in that they have to work much longer shifts under pressure, though the pressures themselves are never so high as those experienced by divers. In times past the mortality among the tunnel and caisson workers from compressed air illness was so heavy that many countries adopted State regulations designed to protect the men by limiting the length of shift and enforcing some sort of gradual decompression. Undoubtedly these regulations have done good, but in the light of modern knowledge and experience they could be improved so as to give greater security to the men while avoiding the costly waste of working time resulting from some of their clauses.

If the civil engineering of the future is going to call for higher pressures than the 40 lb. or 45 lb. per sq. in. that has been the limit hitherto, it is certain that these rules will be found badly wanting, and Sir Ernest Moir in opening the discussion indicated that the time has come for concentrating the available knowledge and experience in producing a rational and practicable code or system for the use of engineers charged with the control and safety of workers in such air pressures. One of the difficulties of the matter is that there is a very great difference in the susceptibility to compressed air illness of different individuals, which at present can only be discovered by trial, so that cases of illness are still to be expected under a system which is quite safe for the average man. Fortunately, a cure is available in 'recompression', which if applied sensibly and at once is certain. Sir Ernest Moir, by his introduction and employment of the 'medical air lock' for applying this treatment, has been the means of saving many hundreds of lives.

Dr. M'Master, who described the latest British experience at the Silent Valley dam of the Belfast waterworks, mentioned many points which seemed to show that secondary factors, such as the temperature and humidity of the workings or a slight vitiation of the air supply, which would be unimportant in diving work, made a marked difference in the number of cases. In the sea we have a continuously graded range of hydrostatic pressures through which the diver can be decompressed as he gradually ascends, but in caisson work the pressures can only be roughly adjusted to the theoretical requirements, so that, though all serious illness was prevented, a good many minor but painful cases of 'bends' had to be treated by recompression, and to cure them it was found necessary to recompress many of the patients to 5 lb. above the pressure at which they had been working (about 35 lb.). This contrasts strangely with experience of divers working at 50 lb. pressure, who when they develop similar symptoms are nearly always cured by recompression to a mere 15 lb. or so, which greatly simplifies and shortens the treatment. But divers, being on board ship, are generally treated immediately the symptoms appear, while men on engineering work may have time to get home before they become ill and then may not present themselves for treatment for some hours. This probably underlies the difference, and the point illustrates one of the difficulties of the engineer: he cannot very well insist on a shift of a hundred men hanging about round the works for an hour or two after they have finished work for the day on the off chance that one of them may develop compressed air illness, but the salvage officer with his handful of divers can easily arrange for there to be no means of getting ashore until the danger period is past.

Mr. Davis, jun., in the course of an interesting review of the history of the subject, described apparatus lately introduced by Messrs. Siebe, Gorman and Co. for very deep diving, including a large steel pressure chamber which is lowered under water so that the diver can enter it on the completion of his job and be hoisted inboard without releasing the air pressure from his body. A long decompression can then be conducted in warmth and dryness instead of under water with much discomfort and fatigue as hitherto, while the ship is free to slip her moorings and get clear or fire blasting charges, which could not otherwise be done until the diver's decompression was finished.

Sir Leonard Hill and Commander Selby spoke of the experimental diving which has been carried out for the Admiralty to more than 300 ft. or 130 lb. pressure, using the Davis decompression chamber and other special devices. One unexpected and rather awkward finding was that, though all the divers were picked men who had been put through a specially searching medical examination, some of them became abnormal mentally (or emotionally as Sir Leonard Hill put it) whilst under this high pressure, and on their return to the surface could remember nothing of what they had been doing before they began to ascend. This effect

might be attributed to the high partial pressure of oxygen in pure air when breathed at 130 lb., or to impurities in the air which was actually supplied to the divers, but Sir Leonard Hill has made tests on the same men which satisfy him that neither oxygen nor carbon dioxide is responsible. It seems to be an extreme case of the subtle change in character and behaviour which comes over some men at less high air pressures and is well known to experienced diving officers. Divers affected in this way generally keep fairly quiet on the subject, as they do not wish to be thought excitable or foolish about their work. The steel decompression chamber was employed to great advantage in these experimental dives, but, as Prof. Haldane pointed out in concluding the discussion, the stages of decompression given to the men were not calculated on the principles which have proved so satisfactory hitherto and do not appear to have given sufficient margin of safety. This is a matter which can easily be rectified if necessary without invalidating the ingenious methods and appliances which have been elaborated for this extremely difficult sort of diving.

The Italian divers now working on the wreck of the *Egypt* at a depth of 400 feet have cut out all danger of compressed air illness and the need for a host of hampering precautions by using the Neufeldt and Kuhnke armoured apparatus, which, though flexibly jointed, sustains the enormous hydrostatic pressure of 170 lb. per sq. in. corresponding to that depth and enables the man inside to breathe air at atmospheric pressure. The gain in safety and economy of working time which results is partly offset by a loss of mobility and manual efficiency as compared with a rubber-dressed diver, but this again is compensated by the elaborate grabs and machinery of the salvage ship. The diver on the bottom has become less the working agent and more the eye and brain directing engines which are lowered to him and worked from above. Conceivably some such semi-automatic system of working may develop in caisson and tunnel work, though it does not seem called for with the pressures likely to be used in the near future. None of the speakers expressed any doubt that all serious illness could be prevented by suitable decompression: the real problem is to key these lengthy decompression periods in with the design of the tunnel, the scheme of work, and the system of shifts, so that they may become something less wasteful and unsatisfactory than hours of enforced idleness passed in dismal steel cylinders.

G. C. C. DAMANT.

Centenary of the Royal Geographical Society.

THE Royal Geographical Society will celebrate on Oct. 21 and the two succeeding days its centenary of inauguration. The Duke of York will open the proceedings on the afternoon of Oct. 21, and delegates from the Société de Géographie, of Paris, and the Gesellschaft für Erdkunde, of Berlin, both of which have already celebrated their centenaries, will present addresses. In the evening, Sir Charles Close, president, Mr. Douglas Freshfield, Sir Francis Younghusband, the Marquess of Zetland, and Dr. H. R. Mill will speak on the history of the Society. On the mornings of Oct. 22 and 23, a series of short papers on "The Habitable Globe" will be read by British and foreign geographers, and in the afternoon of Oct. 23, another series on "Incidents in the History of Exploration" will be read by Lord Lugard, Sir Martin Conway, Sir Francis Younghusband, Sir Halford Mackinder, Col. H. Bury, Mr. J. M. Wordie, and others. The centenary dinner of the Society, at which the Prince of Wales will preside, is to be held on Oct. 23.

Enjoying, on Dec. 31, 1929, the enviable roll of 6369 members, inclusive of 679 women, the Royal Geographical Society emerges from one hundred years of vicissitudes a successful and vigorous English institution. Among our readers there must be some of an earlier generation privileged to retain contemporary recollections of intercourse with intrepid pioneer discoverers who, in their day, lifted the veil in fields of the Society's operations—of, for example, John Rae, Erasmus Ommanney, McClintock, Inglefield, Nares, Leigh Smith; of John Kirk, Grant, Burton, Joseph Thomson. To these elders the centenary proceedings should, for this reason, bring especial interest and point.

Space would not permit notice here of the position of geographical knowledge among the nations at the time of establishment of our home-born organisation. Most of us know, however, that in the early years of the nineteenth century, science was moving definitely towards co-operative effort and in departments—its horoscope was cast that way, though no seer maybe could have forecast our present-day delimitations and specialisation. There sprang into existence new bodies—offshoots of the parent Royal Society—and with each that institution observed terms of amity, though Banks was, perhaps, an unduly obstinate element. Among such were the Geological Society (1807), Institution of Civil Engineers (1818), British Association (1831). As regards individual effort and consequent influence on thought, it is useful to recall that Lyell published the first volume of his "Principles of Geology" in 1830; that year witnessed also the issue of Charles Babbage's argumentative "Reflections on the Decline of Science in England".

Already, however, in the geographical domain, Paris had instituted the Société de Géographie (1821); Berlin, the Gesellschaft für Erdkunde (1828). There was at this period half a world of unknown tracts of land to conquer. All Europe, too, was discussing the achievements of Baron Alexander von Humboldt, traveller and naturalist. This illustrious geographer, welcomed constantly in English philosophical circles, had been elected

a foreign member of the Royal Society in 1815, had dined with the men of science at their club in 1817, accompanied by Arago and Biot, visiting them again, with Kater as host, in 1827. Much was to ensue from these movements and international greetings and friendships.

In the last-named year, another London dining club, the Raleigh, composed mostly of men of travelling proclivities, came into being, and it early realised that a British institution for the advancement of geographical science was a necessity. The idea found current expression in the influential *Literary Gazette*. In the issue for May 24, 1828, over the initials " A. C. C.", the following appeared: " This society [*i.e.* the Asiatic] has certainly filled up one great hiatus . . . but there is another almost equally important to supply . . . I allude to the want of a Geographical Society, a want which is the more singular, as our nation has always been, and still is, the very foremost in promoting geographical discoveries. I am convinced that if such an Association were now to be formed it would in a few years become even more eminently useful than the famous society of Paris."

The outcome of various individual efforts and alliances of views was the foundation of our London society, brought about at a public meeting held on July 16, 1830, and under the advantageous and able chairmanship of John Barrow, secretary to the Admiralty. Viscount Goderich was elected the first president. King William IV. became patron, directing that the Society's title should be the " Royal Geographical Society ". Further, His Majesty granted an annual donation of fifty guineas to constitute a premium for the encouragement and promotion of geographical science and discovery. Four hundred and sixty names were enrolled, forty-three of whom were naval officers, fifty officers of the army, all the leading statesmen of both political parties, including the Duke of Wellington (then Prime Minister), and men of science eminent in all its branches.

The first president, Viscount Goderich, was not, in strict sense, a geographer, neither had his qualifications, so far as one can be aware, any particular scientific bearing or significance. His interests lay in active politics. Notwithstanding these drawbacks, if indeed they were, he seems to have been considered a good figurehead for a Society that had to make beginnings, and a safe one to start with. Educated at Harrow and St. John's College, Cambridge, he entered the House of Commons as the Hon. Frederick John Robinson, filled various subordinate posts, eventually becoming Chancellor of the Exchequer from 1823 until 1827. Upon Canning's death in 1827, he was raised to the peerage as Viscount Goderich, and was Prime Minister for a short while. At the time of election to the presidency of the Royal Geographical Society he was Secretary for War and the Colonies, and a fellow of the Royal Society. He was created Earl of Ripon in 1833.

The *Gentleman's Magazine*, under date Nov. 14, 1831, provides a lively notice of the Society's inaugural session, held in the rooms of the Horticultural Society in Regent Street. We read :

" The first meeting for the season of the Royal Geographical Society took place, the president, Viscount Goderich, in the chair. The room was very much crowded to witness the presentation of his Majesty's first premium of fifty guineas, placed at the disposal of the Society, to Richard Lander, for his discovery of the termination of the Niger, or Quorra, in the sea. After the secretary had read a long paper by Col. Leach on the very interesting question, ' Is the Quorra the Niger of Antiquity ? ' the noble chairman stated that the meeting had been made special for two specific objects, both of great importance to the general purposes of civilisation, but more particularly to this Nation. The first was to present, on this, the first occasion on which the Society had to dispose of the bounty of his gracious Majesty, the prize to an individual certainly the most enterprising of those men who had their names recorded in the annals of geographical discovery. He felt convinced all who heard him would agree that the first award placed at the disposal of this Society by their gracious Sovereign could not be more appropriately disposed of, than by conferring it on an individual whose talents, courage, and enterprise had achieved so much for the advancement of science. His lordship then presented Lander, who rose for the purpose from his seat at the noble chairman's right hand, with the first premium. The latter, in a few words returned his acknowledgments and expressed his deep gratitude. The second proposition was to incorporate the African Association with the Society, which was carried."

Here it should be mentioned that the African Association, referred to as merged in the new Society, was formed in 1788, mainly through the efforts of Sir Joseph Banks and Major Rennell. It had a small but select membership, and, as its name would imply, concerned itself with the geography of Africa and with schemes for forwarding exploration in that continent.

In connexion with the first allotment, in 1830, of the Royal premium to Richard Lander, it may be recalled that his pioneer explorations (and those of Mungo Park) are commemorated by an obelisk, erected last year on Jebba Island in the Middle Niger. A tablet bears the following inscription :

" To Mungo Park, 1795, and Richard Lander, 1830, who traced the Niger from near its source to the sea. Both died in Africa for Africa."

The fifth annual premium at the disposal of the Society took the form of a gold medal, and the practice continued. On the accession of Queen Victoria it was resolved to award two gold medals annually : (1) the Founder's medal ; (2) the Patron's medal.

For a whole decade after inception, the Society met in the apartments of the Horticultural Society. Thereafter, circumstances necessitated sojourns elsewhere, so that the Society became itself a traveller, seeking, yet not securing, a fixed location where all its functions could be performed under one roof. These peripatetic phases are happily ended. Its house at Kensington Gore, occupied in 1913, offered settled habitation, and a long-cherished scheme for additional buildings has come to fruition. It is gratifying to learn that the

structures include a meeting hall with seating for 850 persons; ample library space, worthy of the Society's fine collection of books; with other easements necessary to complete the working scope and social aims of a scientific corporation of this kind.

No reference to the Society would be adequate without testimony to the wonderful and enlightened activity it has consistently displayed in regard to exploration in Africa and in Arctic and Antarctic regions, and help in such undertakings as the successive Mount Everest Expeditions, as well as in others. Scientific men and a vast public are well aware of these services; and, should the lands fail in a measure, there remains the air. Already the Society has encouraged the British Arctic Air Route Expedition by supplying it with "the best instruments it could furnish, and a little of its money".

It remains to add that Admiral Sir William Goodenough has been chosen as the new president in succession to Sir Charles Close, whose term of office ends as the one hundred and first year of the Society begins. Scientific workers generally wish the Society continued prosperity and increased activity in this second century of its existence.

Obituary.

Mr. M. A. Giblett.

When in 1924 it was decided to take up again with renewed energy the development of airships, it at once became clear that a prime necessity was a specialised meteorological service devoted entirely to airship problems. What exactly were those problems was not known: weather forecasting was obviously one, but there were others, not yet formulated, connected with the forces present in the atmosphere which would affect largely the success of airship transport. It was therefore necessary to place the new Airship Services Division of the Meteorological Office under an able Superintendent. The man chosen for this responsible post was at the time a relatively junior Assistant Superintendent in the Forecast Division, but a man who had already made his mark by his scientific ability and outstanding personality.

Mr. M. A. Giblett was then only a little more than thirty years old, having been born on July 15, 1894. He had been educated first at Upton School, Slough, and Modern School, Maidenhead, and then at the Universities of Reading and London. Three years as nautical master on the Cadet Ship *Worcester* under Capt. Sir David Wilson Barker were no doubt responsible for his becoming interested in meteorology, and in March 1919 he joined the staff of the Meteorological Office for training preparatory to going out to the British Expeditionary Force in North Russia on meteorological duties. He sailed for Russia at the end of July 1919 and received his commission as 2nd Lieutenant in the Meteorological Section, Royal Engineers, while actually on the voyage. He was stationed at Archangel, but had been there only a few weeks when the British Expedition was withdrawn. He returned to the Meteorological Office and resumed his duties as professional assistant in the Forecast Division in October 1919.

As soon as Giblett received his appointment as Superintendent of the Airship Division, he set to work with great energy to plan and build up the meteorological organisation which was to be an integral part of the Imperial scheme for the development of airships. At first this scheme only visualised an airship route to India. He found an almost unexplored field before him. It is true that at each end of the route there were highly developed meteorological services, but between the shores of India and the east of the Mediterranean there was no meteorological service and no synoptic charts had ever been drawn for these regions. Further, although practically every country in Europe prepares its own synoptic charts, there was no single chart of Europe on a scale sufficiently large to make it possible to study in detail the changes of weather even in Europe as a whole. Giblett therefore set to work to collect from every possible source observations for the whole area embracing the route from England to India, and from these prepared a series of daily weather charts for a whole year. It was a stupendous piece of work, which is not yet entirely finished, but with the aid of these charts it was possible to study the routes open to airships and to calculate in detail the times it would occupy to travel each route in different types of weather.

Although at that time the route to India was the only one on which it was planned to employ the airships, it was necessary to make a preliminary survey of possible airship routes to all parts of the Empire. In 1926 this became an urgent problem, for the Air Ministry wished to place before the Imperial Conference which was held in that year a scheme for the development of Imperial air transport. This scheme was presented to the Imperial Conference in a book, afterwards published, entitled "The Approach towards a System of Imperial Air Communications", in which sections on the meteorological investigation of the England-India route and on the meteorological organisation in connexion with the development and operation of airship services were written entirely by Giblett. This description of possible routes, the necessary ground organisation for meteorology, and the co-operation required between the meteorological services was a remarkable piece of work and received much commendation at the Imperial Conference: it showed a power of planning and organising seldom met with in so young a man and a 'scientist' to boot.

It had by that time become clear that meteorology would play an important if not the chief

The Electron Theory of Metals.*

By R. H. Fowler, F.R.S.

FROM the point of view of the electron theory, a metal is any solid which is a good conductor of electricity. In attempting to survey roughly the present position of the electron theory of metals, I cannot guarantee that what I say will be everywhere up-to-date, but I shall be satisfied if I can indicate the standing of the theory, as re-established by quantum mechanics.

The Nature of a Metal and Classical Theory.

One may assume that the electron theory of metals effectively began with Drude. At any rate, the triumphant explanation by his theory of the relationship between electrical and thermal conductivities gave it its first real start. The theory, of course, was based, and is still based, on the simplifying approximation, now fairly well justified, that a metal consists of a number of positive ions atoms that have lost one or more electrons more or less permanently resident at the positions required by the lattice structure of the metal crystal, together with the lost electrons free to move about among the positive ions.

The simplest assumption of all, which should be correct for monovalent metals like the noble metals and the alkalis, is that each atom sets loose exactly one electron. The electrons and ions act on one another with the usual Coulomb forces, but to the first approximation the effect of these from the point of view of an electron is to make the interior of the metal an electrically neutral region of roughly constant *positive* potential, such that work must be done to extract an electron and leave it at rest outside in free space at zero potential. Inside the metal, then, to this approximation the free electrons will behave like a perfect gas of uncharged particles of mass m, the mass of the electron. In the next approximation we must recognise that there are regularly arranged spots (the ions) where there is a more or less violent deviation from uniformity; classically, a moving electron will suffer collisions at these spots. The electrical resistance of a metal is determined by the rate at which these collisions dissipate the directed momentum in a beam of moving electrons. The mean space rate of dissipation of this momentum, p, involves a length which one calls the mean free path λ,

$$\frac{dp}{dx} = -\frac{p}{\lambda}.$$

The classical theory included in its initial successes even the prediction of conductivities of the right order for not unreasonable values of λ. But it was ruled out of court by at least one outstanding difficulty, that a perfect gas of one free electron per atom would necessarily contribute $\frac{3}{2}R$ to the specific heat of the metal, that is, 3 calories per gram-atom per degree Kelvin, whereas no comparable contribution is allowable. The vibrations of the massive ions satisfactorily account for the whole (see Fig. 1). There are also other difficulties. The main difficulties could have been turned by supposing that there were only a few free electrons doing all the work; they would then require to have correspondingly long free paths. The surprising effect of small traces of impurity upon conductivity requires these long free paths to be real. But classically it was quite impossible that the free path should be much longer than the atomic spacing in the lattice.

The Quantum Mechanical Revision.

All these and similar difficulties have been entirely removed by the quantum mechanics using

* An abridged version of the twenty-first Kelvin Lecture delivered at the Institution of Electrical Engineers on May 1.

Drude's model unaltered. In fact, it was the dynamics of electrons, not the physical model of a metal, which was wrong and impeding progress. A recognition of some of the more subtle features of quantum mechanics is required to put us on the right track. Let us therefore make a fresh start by discussing the quantum mechanical behaviour of a single electron in the approximate potential field provided by our model of a metal.

Quantum mechanics assigns to any such system a certain number of possible stationary states the energies of which are fixed by the condition that solutions of a certain linear differential equation (Schrödinger's) shall exist, satisfying certain physically obvious requirements. If V is the potential energy of an electron, h Planck's constant, and ∇^2 the familiar operator of Laplace, then this equation is

$$\frac{h^2}{8\pi^2 m}\nabla^2\psi + (V - W)\psi = 0$$

and the possible values of W are the possible *total* energies of the electron. Now our picture requires V to vary rapidly near the metal boundary, and

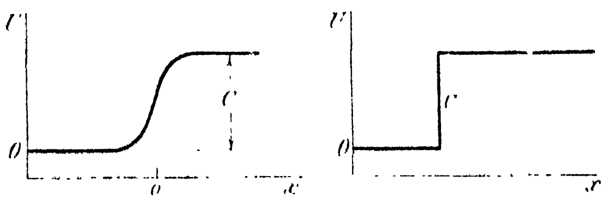

FIG. 2.—The boundary hill.

otherwise to be either 0 or $-C$, according to whether we are outside or inside. The transitional region is probably fairly thin, but we need not at this stage worry about it, for it can be shown that it makes no difference if we take it instead as a sudden step. Again, as this step is fairly high (10 volts or so would be high for present purposes), it makes little difference if we take it infinite. We have then to solve the wave equation

$$-\frac{h^2}{8\pi^2 m}\nabla^2\psi - E\psi = 0,$$

where E is *kinetic* energy, subject to the condition that $\psi = 0$ on the boundary and outside, where V becomes infinitely greater than it is within.*

It is easy to solve this equation if the region within which the electrons are confined is a rectangular box of edges a, b, c. The shape of the box can be shown not to matter for practical applications. For this simple shape the possible kinetic energies are given by

$$E = \frac{h^2}{8m}\left(\frac{r^2}{a^2} + \frac{s^2}{b^2} + \frac{t^2}{c^2}\right),$$

* This is the form to which our physical requirements reduce in such a limiting case.

where r, s, t are positive integers, and the corresponding function ψ is

$$\psi_{r,s,t} = \sin\frac{\pi r x}{a}\sin\frac{\pi s y}{b}\sin\frac{\pi t z}{c}.$$

We now find, on account of the smallness of h and in spite of the smallness of m, that if we take a box of any ordinarily small size, let us say 1 mm.[3], or even a cube of edge $\frac{1}{2}\times 10^{-4}$ cm., a wave-length of visible light, the energies of the possible stationary states lie so close together that we cannot distinguish them for practical purposes from the continuous distribution allowed by classical mechanics. If we then pack into such a box a number of electrons comparable with the number of atoms in the same volume of metal, *and if they do not interfere with one another in any way*, we get a distribution of free electrons indistinguishable from the classical (Maxwellian) distribution of Drude's theory—with the same properties and the same failure as a representation of an actual metal.

Here quantum mechanics makes its first really fundamental contribution in this field, as was first pointed out *for metal theory* by Sommerfeld. It is that one can never, even in zero-order approximation—even in the limit of vanishingly small interactions of the particles' mutual potential energy—treat a composite assembly of two or more electrons by simple combinations of the states possible to one electron. This is not at all (at least to the present depth of our analysis) because of the Coulomb repulsion between them. It applies equally in the limit when this may be supposed to be neutralised. It is not because of other forces which might be regarded as giving the electron a *size*. It is something far more fundamental, entering into the quantum dynamics because its equations are all *linear* in the fundamental wave-function ψ, and entirely foreign to classical particle dynamics because its equations are essentially non-linear, for example in the momenta. It is mathematically like a species of interference due to the superposition of wave systems, with which we are familiar in ordinary oscillating systems, though this analogy must be used with extreme caution. One is apt to think of the de Broglie wave systems associated with particles by the quantum mechanics as wave systems like electromagnetic waves in the ordinary space-time of physics. But the wave system of a pair of electrons, for example, so far as it is anything describable, is strictly a wave system in a six-dimensional space, and so on for more electrons. Electromagnetic or optical analogies are invaluable, but when we wish to use our results by interpreting them in physical space-time, the greatest caution may be necessary.

Whatever may be the correct physical description, the theory is certainly of such a form that possible states of two or more electrons present in a single box together are confined to a selection only of all the states that can be built up by repetition from the states of a single electron. The proper selection can be simply described by saying that *no two electrons can ever be simultaneously in the same stationary state*. This rule holds for all assemblies of electrons, for example, for a single free atom, for which it was first detected semi-empirically by Pauli. It is generally

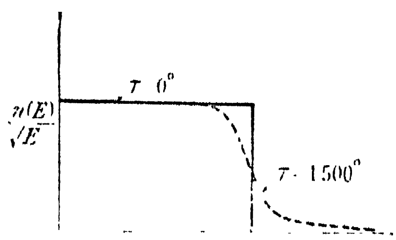

FIG. 3.—The distribution law at 0° and 1500° Kelvin.

now known as *Pauli's principle*. The principle must be strictly interpreted. We shall have to admit later on that electrons have a spin of their own and an associated magnetic moment which is capable of exactly two orientations, along and against any magnetic field. These two orientations may be regarded as the two possible values of another quantum number which, with r, s, and t, makes up four for each electron. The strict enunciation of Pauli's principle is, then, that in any assembly of electrons no two electrons may ever have the same *four* quantum numbers.

I have deliberately stressed the independence of Pauli's principle of any crude mutual potential energy between the electrons. This is the correct and only not misleading attitude to adopt at the present stage of development of the theory. But perhaps if the recent researches of Eddington prove ultimately fruitful, one may hope to fuse together Pauli's principle and Coulomb interactions as two manifestations of a single, more comprehensive scheme.

Quantum mechanics cannot yet predict that electrons will in fact obey Pauli's principle; it can as yet only show that if initially all electrons obey this principle, they will continue to do so for ever. In fact, it seems they always do obey it. As has been said, it was its introduction into metal theory by Sommerfeld that gave metal theory its new start. Allowing for Pauli's principle, we find that the number of free electrons with kinetic energies between E and $E+dE$ in a unit volume of an idealised metal, instead of being given by the familiar distribution law of Maxwell,

$$n(E)dE = A'e^{-E/kT}E^{\frac{1}{2}}dE, \qquad (1)$$

is given by the slightly different law of Fermi and Dirac,

$$n(E)dE = \frac{4\pi(2m)^{\frac{3}{2}}}{h^3}\frac{E^{\frac{1}{2}}dE}{1+e^{E/kT}/A'}. \qquad (2)$$

A, A' are constants so adjusted that the total number of electrons of all energies is correct—perhaps the equivalent of one per atom for a monovalent metal. It will be noticed that equation (2) reduces to equation (1) when A is very small, but there is no resemblance when A is large. When A is large its value is given approximately by

$$A = e^{E'/kT}, \quad E' = \frac{h^2}{8m}\left(\frac{3n}{\pi}\right)^{\frac{2}{3}},$$

where n is the total density of the electrons.

Just here is where the very small mass of the electron takes effect. Obviously, A depends on the mass, and turns out to be large for electron densities of the order of metallic ones, so large, in fact, that the distribution would be quite unclassical even, for example, for copper at 1500° K. This is shown clearly by the actual distribution law sketched by Nordheim in Fig. 3. At ordinary room temperatures, and even well above, the distribution is such that, nearly enough,

$$n(E) \propto E^{\frac{1}{2}} \quad (E < E'),$$

$$n(E) \propto e^{-E/kT}E^{\frac{1}{2}} \quad (E > E').$$

What happens is that at all such temperatures practically every possible electronic state for which

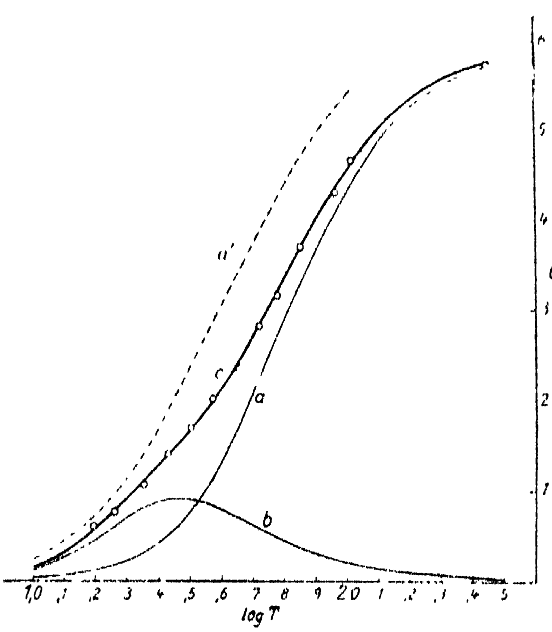

FIG. 4. Specific heat of grey tin. Circles indicate observed values. Curves a and a' are Debye curves which cannot be made to fit; curve c is $a+b$, and b is here interpreted as the contribution of the electrons.

$E < E'$ is occupied by its one electron, while for $E > E'$ practically all are empty. The very few electrons that are there are too few to worry each other, so that they can obey Maxwell's law.

We find at once that the specific heat difficulty melts away. One can see at a glance from Nordheim's figure that the change of energy content with change of temperature must be very small. Detailed calculation confirms this and gives the total kinetic energy, $E_{kin.}$,

$$E_{kin} = \frac{\pi}{40} \cdot \frac{h^2}{m}\left(\frac{3n}{\pi}\right)^{\frac{5}{3}} + \frac{2\pi^3 mk^2T^2}{3h^2}\left(\frac{3n}{\pi}\right)^{\frac{1}{3}},$$

from which the specific heat contribution is utterly negligible. It is, in fact, *too* small, and later more refined calculations by Bloch make it rather larger generally and possibly much larger in a limited region, so that it is able to account in a most satisfactory way for certain interesting specific heat anomalies such as have been found by Simon at fairly low temperatures for grey tin (see Fig. 4) and other metals. The constant term, on the other hand, is large; the electrons have a large 'zero point energy'. But this is without importance for metallic phenomena.

The New Conduction Theory.

We have so far considered equilibrium states only, and have still to apply the new theory to conduction problems, states of steady flow.

In a preliminary survey, Sommerfeld revised Lorentz's calculations by using the new equilibrium $n(E)$ instead of Maxwell's, and showed that to give observed conductivities the mean free paths must be very long. As we have seen, this is all to the good for empirical reasons, but classically a free path in a metal of from 10 to 100 interatomic distances seems to be nonsense. Quantum mechanically, however, it is just what we must expect, as the work of Houston, Bloch, and Peierls has shown. For if one examines the behaviour of an electron now no longer in a region of uniform potential but in a potential with variations which are perfectly space-periodic, one finds that though these periodic variations alter the energies of the stationary states of an electron in the box, yet they do not affect at all its power to move freely through the box in a given direction.

Such perfectly periodic variations of potential can correspond only to a metal which is a perfectly pure, perfect, single crystal at zero temperature, assuming that then all the ions are at rest relative to each other. But in such a substance the mean free path of an electron with a kinetic energy of a few volts should be infinitely long, and the substance should possess an infinite conductivity. One can give an analogy to these long or infinite free paths from physical optics. Light in passing through an optically homogeneous medium such as air or many crystals is to a first approximation not scattered or absorbed at all, though every molecule is a potential scattering centre. As was first shown by the late Lord Rayleigh, it is only local deviations from perfect uniformity that scatter the light; deviations which in a dust-free gas are probably fluctuations of concentration, and in a crystal flaws and foreign bodies. Just so the de Broglie waves of the electron are not scattered by perfectly regular lattices but only by random deviations from perfect regularity, due to thermal agitation, to strains, or to impurities.

This description, however, is still not entirely adequate. It is quite certain, both theoretically and from X-ray evidence, that at the absolute zero of

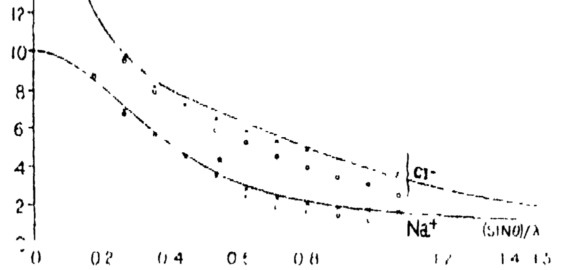

Fig. 5.—Comparison of F values deduced from observation with those calculated from theory. F is plotted as function of $\sin\theta/\lambda$ for Na^+ and Cl^- ions, θ glancing angle, λ wave-length in A. Curves show values of F for distribution of electrons calculated by wave mechanics. Crosses show values of F deduced from observation assuming zero point energy; circles show values of F deduced from observation, assuming no zero point energy.

temperature the ions of a metal crystal are not at rest in their positions of equilibrium but oscillating about them, the whole crystal containing a considerable irreducible zero point energy of oscillation. This fact (see Fig. 5), which at first sight appears destructive of the theory, urges a closer investigation, for conductivities certainly tend to infinity in favourable cases as the temperature tends to zero, even if supra-conductivity does not appear. It is then found that one cannot properly discuss the mean free path without investigating in detail the exchange both of energy and momentum between an electron and the lattice, which must occur when a free path is terminated.

One can analyse the motion of the ions in the lattice into elastic waves in the manner of Debye in his theory of specific heats. In order that a free path may be terminated it is necessary—

(1) That an electron of energy E and momentum p shall be transferred to E', p', which latter, by Pauli's principle, must be a *vacant stationary state*.

(2) That the oscillatory state of the lattice shall

change to a new state, absorbing the energy and momentum differences $E - E'$, $p - p'$.

At high temperatures there is comparatively little difficulty in fulfilling these requirements, but at low temperatures Pauli's principle makes it difficult for an electron to do anything but gain energy, while the oscillations of the lattice, being almost entirely in their lowest state, find it almost impossible to lose energy. Thus the chance of exchanges (in spite of zero point energy), and therewith the resistance, rapidly diminishes.

Quantitative investigation on these lines has been carried through exactly for high temperatures and yields an electrical resistance varying as T, in admirable agreement with experiment. At low temperatures the investigation is much more difficult, and theoretical resistances varying like T^3, T^4, or T^5 have been obtained. While any of these is sometimes in fair agreement with experiment (see Fig. 6), it seems to me that the final investigation has yet to be made. We may, however, rest well content with what has been done until the next step can be taken in relating the theory to supra-conductivity. This step has not yet been taken. It may be connected with the theory of magnetic effects, about which there is much to be learnt from Kapitza's experiments. There is as yet no theory which accounts for his results, and, interesting as they are, we must perforce pass them by here.

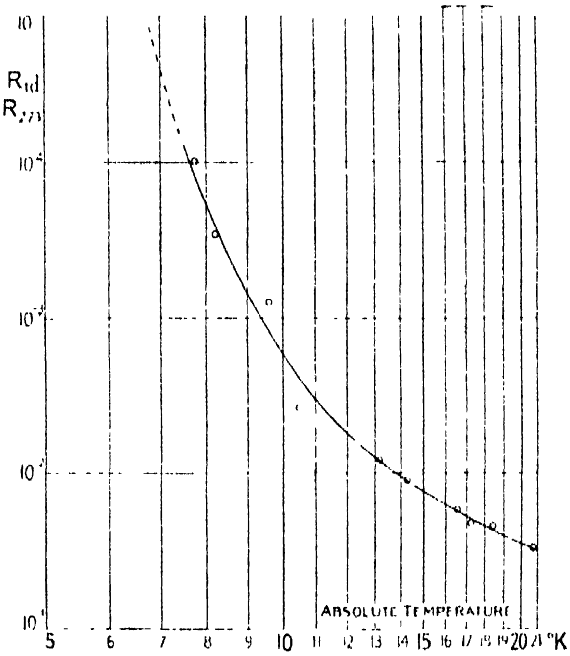

FIG. 6.—Change of the ide[illegible] of lead near the absolute zero plotted on a logarithm[illegible] ie resistance varies like T^4 in the region of 15°–20°, but is already varying faster than T^5 below 10°.

Thermo-Electric Effects.

Before leaving the subject of conductivity, I should record that the theory as so far developed gives an explanation of reversible thermo-electric phenomena which in a general way is entirely satisfactory. The various thermodynamic relationships are of course preserved, and the Thomson and Peltier coefficients are given values of the right general order of magnitude and type of variation with absolute temperature, even by Sommerfeld's version. The refinements introduced by Bloch and Peierls could no doubt be made to give a very satisfactory account for many metals.

Emission of Electrons.

We have so far tacitly assumed that all the electrons stay for ever in the metal, as of course they would have to do if the potential step at the surface were infinitely high. But if the step is finite, no part of what precedes is effectively altered, except that formula (2) indicates that there are present in the metal at any time a certain number of electrons (depending on the temperature) with sufficient energy to escape. Since free paths are rather long, it is sufficient to ignore the periodic lattice structure in the potential and consider what happens when an electron of kinetic energy E falls on a potential step or hill, in which to a first approximation the potential is a function of the distance from the boundary alone. It is easy to show that in such a problem the motion of the electron parallel to the surface is unaffected, and the problem resolves itself into a one-dimensional one. We can now confine attention to a stream of electrons, of energy W in their motion normal to the surface, incident from inside the metal on potential hills of various shapes. Typical natural and idealised boundary hills are shown in Fig. 7.

Now the classical solution of this problem is rather rigid and gives no scope for the observed variety. The electron would then always come out if $W > B$, the summit height of the hill, and never if $W < B$. In the quantum mechanics, however, things are very different. The electron never comes out if $W < C$, the *final* height of the step, but always has a non-zero chance of coming out if $W > C$, even though $W < B$. If we call this chance of emergence $D(W)$, and $N(W)dW$ the number of electrons incident on unit area in unit time with normal energies between W and $W + dW$, the total saturated current I per unit area which the metal can emit (supposing it is all collected as in the usual thermionic measurements) is given by

$$I = \epsilon \int^{\infty} N(W)D(W)dW.$$

Now on Sommerfeld's theory we know $N(W)$ (Fig. 8), and this theory is amply accurate for the present

application. We can calculate $D(W)$ and hence the thermionic current I. I think one may say that these calculations are successful, for they show that

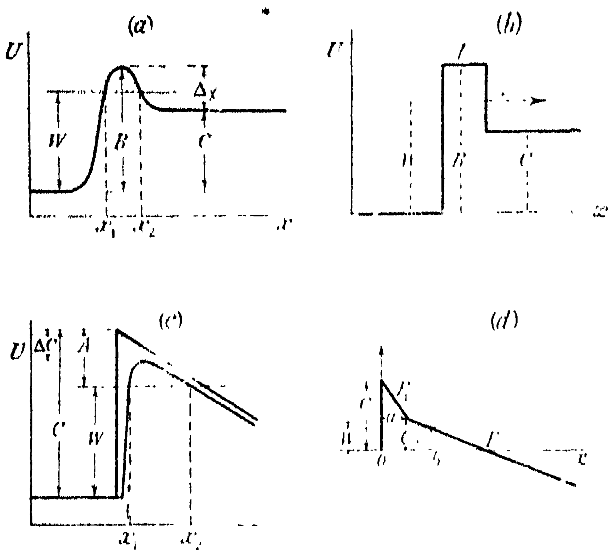

FIG. 7. Typical natural and idealised boundary potential hills. (*a*) A natural type of hill when an electro-positive monomolecular layer is present and the force is ignored; (*b*) the same idealised for simplicity of calculation, but without loss of any essential feature; (*c*) an idealised hill (a precipice) with a strong external field of force helping to pull out the electrons, and the same hill modified by the image effect (this modification explains the Schottky effect, and the unmodified hill the ordinary auto-electronic discharge); (*d*) a hill with two slopes, one intrinsic and the other that of the applied external field, explaining the combined effect of strong fields and monomolecular surface layers.

$D(W)$ is sensitive to the nature of the hill, that is, *to the nature of the surface layer, which may often be a layer of impurity present by accident or design*. The theoretical current is given by the formula

$$I = AT^2 e^{-\chi/kT},$$

where A and χ are constants characteristic of the emitter. This is of the well-known proper empirical

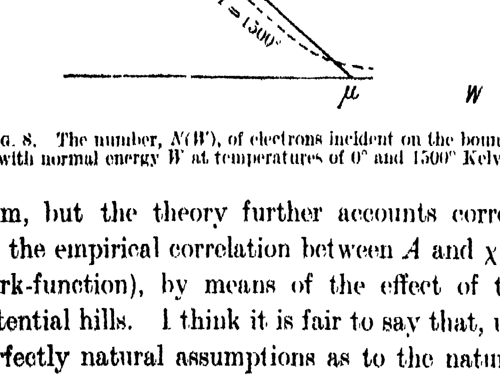

FIG. 8. The number, $N(W)$, of electrons incident on the boundary with normal energy W at temperatures of 0° and 1500° Kelvin.

form, but the theory further accounts correctly for the empirical correlation between A and χ (the work-function), by means of the effect of these potential hills. I think it is fair to say that, using perfectly natural assumptions as to the nature of the boundary hill, the usual phenomena of emission of electrons, from hot metals, under very strong electric fields, and under the influence of light, can to a first approximation be accounted for to our complete satisfaction.

It is interesting to observe that an electron can go through a region in which its kinetic energy is apparently negative. Its chance of going through is large if the region is very thin, and dies away exponentially as the region widens. When we consider the wave nature of the electron, regarding it as a train of de Broglie waves, we see that this is closely analogous to a well-known phenomenon of physical optics. If light is incident on a plane interface at an angle greater than the critical angle, there is total internal reflection. But if the second medium is very thin and followed by a third medium the same as the first, there *is* a weak transmitted beam formed in the third medium after all.

MAGNETISM AND FERROMAGNETISM.

So far we have been able to proceed ignoring the specific interaction of the Coulomb forces between each pair of electrons or ions. But Heisenberg has shown that when these are taken into account, and also the magnetic moments of the electrons themselves, the theory, though still in a larval stage, gives a beautiful account of ferromagnetic phenomena.

The first step in this part of the theory was due to Pauli and concerns the approximation in which we still neglect the Coulomb interactions. We infer from atomic spectra that every electron has a spin or moment of momentum $h/4\pi$, that is, a one-half quantum, and at the same time a magnetic moment of one Bohr magneton. The Bohr magneton is the magnetic moment of any electronic orbit in any atom in which the electron has just one unit, $h/2\pi$, of orbital angular momentum. Thus the ratio of magnetic moment to angular momentum for the intrinsic spin of the electron must be just double the ratio of these quantities for any electronic central orbit. (Incidentally this fits beautifully into the later versions of relativistic quantum mechanics which we owe to Dirac.) Since, then, free metallic electrons carry each a Bohr magneton the axis of which can be turned along and against any imposed magnetic field, the alkalis and noble metals would be strongly paramagnetic with a temperature-dependence similar to that of the classical gas theory of Langevin, if it were not that once again Pauli's principle intervenes to prevent the accumulation of the electrons at any reasonable temperature into states in which an appreciable excess are orientated along the field.

The susceptibility of such an electron gas is not

difficult to work out exactly. It turns out that there is theoretically a slight residual temperature-independent paramagnetic susceptibility of the same order as the usual diamagnetic one. In combination with a normal diamagnetic effect from the ions, this accounts very satisfactorily for such paramagnetic effects as are actually observed in the lighter alkalis. These effects are really extremely small, and from here on we shall ignore them and speak as if our idealised metals, neglecting specific interaction effects, were magnetically neutral. We have, of course, assumed here that the ions are inert, as they would be for the monovalent ions of the alkalis and the noble metals, which contain only completed groups of electrons.

In introducing his theory of ferromagnetism, Heisenberg points out that as a *formal* explanation of the whole body of ferromagnetic phenomena, Weiss's familiar theory is completely satisfactory. The essence of the theory is that there must be in the total internal energy of a ferromagnetic substance a rather large term which depends in a certain way on the magnetisation. Granted the existence of this term, known as Weiss's molecular field, everything fits together as it should, but the difficulty has been to account rationally for its existence, since the actual magnetic energies involved are some ten thousand times too small. This defect quantum mechanics and Heisenberg have now removed.

Heisenberg starts by directing attention to the *gyromagnetic anomaly*. When a bar of metal is magnetised it requires simultaneously a proportional angular moment of momentum which can be actually measured if the suspension is sufficiently delicate. Since all atomic orbits of electrons have one constant ratio, $e/(2mc)$, for magnetic moment to mechanical moment of momentum,* one expects to observe a constant ratio between the magnetisation and the angular momentum generated, from which e/m may be calculated. The constant ratio is found, but for all ferromagnetics, for which alone until quite recently experiments have been made, the value of e/m so observed has exactly twice its expected value. This is the so-called anomaly, but the observed value is exactly what one would expect if the magnetisation were contributed entirely by the orientation of the intrinsic spins of electrons and not of their orbits at all. We assume, therefore, that the magnetism of a ferromagnetic is derived entirely from the orientation of the spins of its loosely bound or free electrons. Heisenberg then finds that the terms needed to account for Weiss's field are to be found in the effect of the Coulomb forces—the electrostatic repulsions and attractions—which have hitherto been disregarded in our theory. In this step, however, we meet one of the most elegant subtleties of quantum mechanics which I will try to explain by using the simplest possible example.

In order to get a feasible method of approach to the interaction problem, Heisenberg idealises the metal in a different way from that which we have used hitherto. He imagines the crystal lattice to be composed of *atoms*, not ions, and expanded by continuous growth of the lattice constant until all the atoms are rather far apart. This looks so different a model as almost (if accepted) to deny the validity of our old one—but this inconsistency is only superficial, and it has, in fact, been shown by Bloch (at least, I think his argument is valid) that one can get similar effects to Heisenberg's by putting the interactions into our original model; the necessary technique is, however, more complicated and we may follow Heisenberg, recognising that there is nothing inconsistent with our previous model in his method of approximation, even if the magnetic and conduction electrons are the same, as recent experiments seem to suggest. We must therefore discusss the possible stationary states and energies of a large number of regularly arranged similar atomic systems each containing one, two, or a few electrons in similar orbits sufficiently loose for the interactions to matter. The large number, though essential to represent a metal, introduces merely complications of detail but none of kind; we can confine attention to *two*, and for purposes of illustration to two hydrogen atoms in their normal states.

Now here again the linearity of the wave equations comes in. It is impossible, when account is taken of the electrostatic interactions, for there to be a stationary state in which one electron is in one atom and the other in the other. If we could start with a particular assignment we should still find, after a time depending on the distance apart, that the electrons had changed places. When the atoms are fairly close together these exchanges become quite rapid and the corresponding energy term—the electrostatic interchange energy, as it is sometimes called—quite large and nearly comparable with the unperturbed energies. The system, of course, has actual stationary states (in fact, two) of definite energies, which may be regarded as built up by superposition in definite ways out of the unperturbed solutions with the electrons in their separate atoms.

* Here c is the velocity of light and e/m the ratio of charge to mass for the electron.

The two states have quite different energies which vary differently with the distance apart of the atoms (see Fig. 9). In one of them the electron spins and magnets balance each other out and the system has no magnetic moment. In the other the spins have to be parallel and the system has a magnetic moment of two Bohr magnetons. The energy difference of the two states, due to the electrostatic interchange term, is of altogether greater order, at least when the atoms are fairly close together, than the magnetic energy terms themselves. Now suppose we consider a number of such pairs set parallel and far apart from each other in a magnetic field. The magnetic field will alter the distribution of all the electron magnets (to what exact amount, of course, it is part of Heisenberg's problem to calculate), and therefore

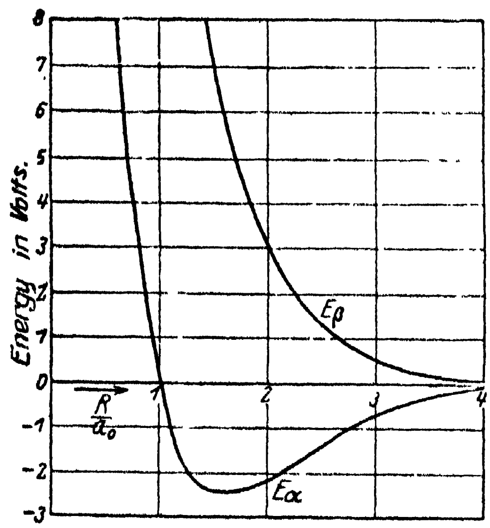

FIG. 9. The potential energy of two colliding hydrogen atoms, showing the two quite distinct values which it can take.

the relative number of pairs which are neutralised or possess a magnetic moment, and of course the orientation of the latter It will therefore have to alter the distribution of the pairs among their two stationary states, and therewith the energy content of the whole system, and that, too, by an amount depending on the magnetisation, which is very large compared with the magnetic energies themselves.

Here is the true origin of Weiss's molecular field! The atoms in a real metal lattice, each with an electron in a similar orbit, present a problem exactly similar in type, though it requires the help of abstract group theory conveniently to carry through the calculations. We can now safely proceed to the result of these calculations. Heisenberg finds, for a metal in which there is one 'active' electron per atom, that in the equilibrium state the magnetisation σ is given by a root of equations which are essentially the same as Weiss's. Heisenberg neglects all interactions except those between nearest neighbours, and his final equations contain a quantity J_0 which is practically the interaction energy giving the energy separation between the stationary states of a pair of neighbours. In order that the metal may be capable of ferromagnetism, J_0 must be *positive*: in order that the Curie point may be at a reasonably high temperature, J_0 must be rather large. Heisenberg can show in a general way that these conditions are rather difficult of fulfilment and that ferromagnetics might be expected to be rare and to be found only (as they are) among the metals of least atomic volume—a genuine triumph! *

CONCLUSION.

It must not be thought that I am too blindly optimistic about the present position of the theory of metals. There is much still to be done. I am optimistic to this extent—that I think that quantum mechanics, at our disposal to-day, is entirely adequate for a final electron theory of metals, or for any other physical theory which can treat the velocity of light as infinite. But metal theory is still far from adequate; I mean, of course, that part of the complete theory of metals is to deduce from the properties of atoms and the principles of quantum mechanics that a collection of, say, copper atoms with a reasonable energy content will form a metal and not, for example, a gas. The theory must next specify what simplifications may or may not be made in the further treatment of conduction.

In the work I have described these more fundamental problems have not been touched, but I think that a very promising beginning has been made on them by Slater. It appears likely that this work and the complete theory when it comes will very greatly modify the simple model which we have used hitherto. But part of my faith in quantum mechanics is derived from the fact that for any physically reasonable model it provides results which are always in good sensible accord with the requirements of experience. Theory and experiment may both be pushed ahead in the confident expectation that we are on the right lines and that progress will be sure and not particularly slow.

* Bloch (*Zeitschrift fur Physik*, vol. 61, p. 206, 1930) has still further advanced the theory by improving it for low temperatures with the help of very important new methods developed by Slater (*Physical Review*, March, 1930).

Printed in Great Britain by R. & R. CLARK, LIMITED, *Edinburgh.*

part in the development of airship transport, and that airship-meteorology must be developed along with airship-architecture and airship-mechanics. It was therefore only natural that when the Air Ministry despatched a mission to South Africa, Australia, New Zealand, and Ceylon to confer with the governments on airship routes and to survey possible sites, Giblett should be a member. On this journey, which lasted from May 5, 1927, to December 17, 1927, Giblett met the official meteorologists in the Dominions mentioned and also those in India and Egypt. Everywhere he made friends and impressed everyone with his scientific judgment and enthusiasm for his scientific work. He explained the problems and was highly successful in enlisting the co-operation of the various meteorological services in initiating the meteorological observations, both surface and upper air, on which alone a reliable survey of the atmosphere can be made.

During Giblett's absence the collection of data of upper winds and thunderstorm frequency in all parts of the world, which he had planned before leaving, had proceeded apace, and progress had been made in an investigation into the structure of the wind which will be a piece of classical work when the results are published.

The time had now arrived for making detailed plans for the journeys of the new airships *R100* and *R101*. At first it was proposed that both these airships should be employed on the India route, but early last year the plans were altered and it was decided that *R100* should go to Canada instead of to India. This necessitated a new and rapid meteorological survey of the Atlantic crossing which could only be made with the aid of synoptic charts. Much work was done, mainly by Giblett personally, to calculate the time taken to reach Canada on different routes under different weather conditions. In co-operation with the navigators he carried out on paper a number of crossings of the Atlantic. A date of departure would be chosen and then from the synoptic chart of the day a course would be laid down. The next day's chart showed where the airship would have been and then the course for the next day set. In this way the whole crossing was worked out in detail. A large number of occasions were studied and the statistics of the time taken on the different routes were discussed. An interesting result came out, namely, that the track across the north Atlantic, in spite of its greater winds and bad weather, was more frequently a better crossing than one farther south where the weather as a whole is much better. This was against the opinion generally held.

Simultaneously, in conjunction with the wireless staff, detailed plans for the collection of data by the airships when in flight were worked out, and areas delineated in which the ship would receive its forecasts from specified meteorological services, these being the meteorological services of London and Canada on the Canada route and those of London, Malta, Egypt, and India on the India route. A scheme for handing over responsibility from one service to the other was worked out in great detail.

Those of us who worked with Giblett were much impressed with the thoroughness with which he planned his organisation. It is impossible here to go into any further details of this work, but sufficient has probably been said to indicate the remarkable organising powers of Giblett. He was given almost complete freedom in working out his plans, and he never failed in the trust reposed in him.

There is not space to say much about his purely scientific work: but Giblett was one of our very best meteorologists. He worked on turbulence, and applied the new work of Taylor and Richardson to the problem of evaporation from a large expanse of water. He was an enthusiastic follower of the Bergen school of forecasting and made use of the new knowledge of 'fronts' in all his forecasting for airships. The importance of atmospheric disturbances for the safety of airships led him to a detailed study of line squalls and water spouts, and his paper on line squalls, which he read before the Royal Aeronautical Society in 1927, contains the best review of our knowledge on this subject which exists.

Added to his ability as a man of science and as an organiser, Giblett possessed a charming personality. This was a great asset, for it endeared him to the technical officers with whom he worked, and he became a close personal friend to Colmore, Scott, and Richmond. It is heartbreaking to those of us who worked during the last five or six years with Giblett to see all his plans destroyed before they were put to the test, and the loss of so much knowledge and experience is a disaster compared with which the material loss is absolutely insignificant.

Giblett leaves a widow and daughter three years old, to whom, as well as to his mother, the sympathy of all will go out.

G. C. SIMPSON.

LIEUT.-COL. V. C. RICHMOND, O.B.E.

VINCENT CRANE RICHMOND, who was killed in the disaster to the *R101* on Sunday, Oct. 5, was the Assistant Director of Airship Development (Technical) at Cardington, and as such was responsible not only for the design work there but also for the control of airship research. He was born on Jan. 21, 1893. His education at the Royal College of Science, London, was that of a physicist rather than a mathematician, and it was indicative of his capacity that he was undertaking work that needed not only an understanding of those subjects but also considerable engineering knowledge as well.

Richmond's connexion with airships dates from 1915, when he was dealing with the manufacture of envelopes for non-rigids for the R.N.A.S. The design of the gas-bags and the methods of taking the stresses in the *R101* showed many signs of his experiences of those days. His experience of rigid airships was chiefly commenced in 1919, when he was attached to the Inter-Allied Commission in

Germany, in the department that dealt with the surrender of airships. It is probably no secret now, that as a result of his experience there he was convinced of the folly of the school of thought, then in the ascendency, that all the Zeppelin work then on hand should be destroyed and the organisation disbanded. Just how far his opposition to this policy influenced the official decision to reverse it, one outside those august circles is not permitted to know, but the many tributes that members of the Zeppelin Companies' staff have paid to him show that they have a full appreciation of his courage and far-sightedness upon this occasion.

One of Richmond's earliest problems at Cardington was that of carrying out full-scale experiments for the elucidation of many unsolved problems upon the co-ordination of wind-tunnel and full-scale test results. At this stage there were alarming discrepancies, and the existing information upon heavier-than-air craft was not of great use, as the conditions were so essentially different. The *R34*, upon which he carried out his experiments, then provided a fresh problem by breaking away from the mast and proceeding upon her now historic flight over the North Sea and back. The present-day British mooring system shows many signs of Richmond's ingenuity in dealing with the weaknesses made apparent by that mischance. It is no mere expression of opinion to say that it is completely successful. During last spring the *R101*, at the new mooring-mast, weathered one of the worst gales experienced in Great Britain for many years past.

Richmond's position as designer of the *R101* presented him with many problems that would have defeated men of less breadth of vision. He had to hold the balance between a set of conflicting requirements that must have been almost unparalleled in the history of scientific research. He had to hammer out an almost entirely new principle of construction that should overcome the weaknesses in previously accepted methods, as made apparent by the failure of the *R38* some years before. His materials were new and none too thoroughly investigated then. It was decided that every theory about which there was any possible doubt should be supported by a test upon a full-scale section of the structure. He had to satisfy a panel of independent experts who would have the eventual responsibility of certifying his ship as airworthy. Finally, he had to collaborate, as the necessity arose, with the designers of the sister ship, the *R100*.

During the last few years Richmond had been lecturing upon airship design at the Royal College of Science, South Kensington, and whatever the future of airships may be, the information disseminated through that source, and his students' personal remembrance of their teacher, will remain as, at least, one monument to his memory. "Operæ pretium est."

WE regret to announce the following deaths:

Dr. D. Adamson, past president of the Institution of Mechanical Engineers, on Oct. 11, aged sixty-one years.

Dr. H. R. H. Hall, Keeper of the Egyptian and Assyrian Antiquities, British Museum, on Oct. 13, aged fifty-seven years.

Prof. Paul Wagner, director of the Agricultural Research Station at Darmstadt from 1872 until 1923, on Aug. 26, aged eighty-seven years.

Dr. C. Powell White, for some years director of the Helen Swindells Cancer Research Laboratory at the University of Manchester, and pathologist at the Christie Hospital, Manchester, and a member of the executive of the British Empire Cancer Campaign, on Sept. 26, aged sixty-three years.

News and Views.

A FEATURE of the developments of electron theory dealt with by Mr. R. H. Fowler in the Supplement which we publish in this issue of NATURE is the extent to which older ideas have proved amenable to the requirements of quantum mechanics. The 'electron cloud', for example, has persisted, to provide, with certain modifications, the physical picture upon which most aspects of the theory are still developed, and the conception of a work-function for the passage of an electron through a surface has again emerged in the expressions for thermionic emission in a form little different, for practical purposes at least, from its original one. The amount of co-ordination and clarification of ideas effected by the quantum mechanics is nevertheless enormous, and it appears the more remarkable when the wide range of the electrical properties of metals to be explained is taken into account. Whilst there are still outstanding problems, notably in connexion with supra-conductivity and magnetic phenomena, as well, of course, as the fundamental ones referred to by Mr. Fowler at the end of his lecture, it will probably be generally admitted that his expectations are not unduly optimistic. Mr. Fowler has very modestly done less than justice to the importance of his personal contributions to the subject, which have been published in "Statistical Mechanics" and in numerous papers in the *Proceedings of the Royal Society* and the *Proceedings of the Cambridge Philosophical Society*.

As will be seen from Mr. Fowler's May lecture, the lines of experimental research which theory indicates as being probably most profitable at the present time would seem to be the electron emitting properties of surfaces, the properties of single crystals, galvano-magnetic phenomena generally, and supra-conductivity. Probably no stimulus would be required for the first two in any event. Both have practical applications of much importance, one in connexion with thermionic devices and photoelectric cells, and the other as the rational line of approach to a proper understanding of the elastic and electrical properties of the ordinary metals of engineering practice. The investigations of the magnetic properties of materials that are called for do not, however, appear likely to be capable of such applications, and the same is true

to an even greater extent of the results to be obtained from low-temperature work. Magnetic and cryogenic laboratories are expensive to equip and maintain, and progress in these two directions may prove to be slower.

"THIS very year of grace", said Sir William Hardy, in his presidential address to the British Association of Refrigeration, "is not far from the three hundredth anniversary of the birth of modern science." Science is still in its raw youth; yet when we think of what it has already achieved, both as a philosophy and as a utility, the belief in an indefinite future of progress upwards for humanity scarcely surprises us. Sir William Hardy told his audience that he would leave the hillock which offered a view of the relation of science to industry in order to climb a hill whence the outlook on modern science was wider. Those who journeyed with him must have returned refreshed in spirit and eager to explore what lies beyond. Modern science is both a mode of thought and an austere discipline; it regards nothing as impossible, takes nothing for granted, and accepts nothing on authority. Modern science, which like other philosophies gives one of the many answers to the questions where man is and whither he is going, is not merely a docile slave which ministers to our comfort and our convenience; yet it cannot help contributing directly to the material well-being of mankind, for knowledge leads to mastery over the forces of Nature. Indeed, so great and so obvious is the material utility of science that its deeper significance has become obscured. The great utilities of science have been won not by aiming at them; they are the result of the organic growth of a vast body of interrelated knowledge. Natural science is a philosophic system which a man who would serve industry has to master as well as he can, and the more mastery he has the better services can he render.

EXCEPTIONS to the paradox of the utility of science, that the short cut to utility is to forget it, are apparent only, said Sir William Hardy; they exist when the needs of industry are ahead of scientific knowledge. Thus the search for new industrial metals is largely a matter of hit or miss, of trial and error. Astonishingly successful as the method has been, it would be dropped immediately if we knew enough about the solid state, for the development of fundamental laws results in an immense saving of time and labour. Assistance can be rendered to the fishing industry by improving the treatment of fish oils, but here again the shortest road to utility lies in the direction of an increase by experiment of the general body of fundamental knowledge. While it is true that material progress follows advance of thought and the development of fundamental considerations, we must not overlook the effect which such material progress itself has on our whole outlook. The first reaction to Copernicus's deposition of man from the important position which ancient belief and ancient science had given him was anger, and the second pessimism. He owes the re-establishment of confidence in himself and belief in his destiny to the tremendous triumphs of modern science both on the theoretical and on the practical sides. Yet the theory of progress needed a century to gain sufficient ascendancy to open the way for the tremendous optimism which seems so natural to us. Sir William Hardy also referred to the part which the State should take in fostering science on behalf of industry. Industry still regards science as a visitor to be warmly welcomed only in times of emergency. Mistrust of science will prevail so long as a polite education, in which a training in scientific method and outlook has no place, is accepted as complete. The collaboration of the State in scientific advancement is legitimate and necessary, but in the future a greater share of the burden must be shouldered by industry itself, for applied science cannot grow except in association with fundamental science.

THE incoming president of the Royal Aeronautical Society, Mr. C. R. Fairey, delivered his presidential address on Oct. 9, taking as his subject "The Growth of Aviation". Comparing the feats of the pioneers with present-day achievements, Mr. Fairey remarked that whereas in 1903 the distance performance and its duration were 852 ft. and 59 sec. respectively, the corresponding figures for the present time are about 5000 miles and 67 hours. In 1903 flight was just above the ground and speed about 30 miles per hour; recently a height of 42,000 ft. was reached and the record for speed is 357 miles an hour. Progress has been continuous during the past twenty years, but it seems that, at any rate as regards speed and height, the limit for present methods will soon be reached. Military aviation has, in the past, provided the greatest support to the growth of the technical side. Commercial aviation has made remarkable strides and with present progress should soon be self-supporting. Australia had half the mileage of Great Britain in 1922, but in 1929 had equalled it; Canada had less than 200,000 miles in 1923, passed the total for Great Britain in 1928, and in 1929 nearly doubled it. The rate of expansion in both countries has been exceeded only by the United States. The total mileage of commercial aircraft in the United States in 1929 was 104,000,000 miles, an increase of 375 per cent of that for 1928 and equal to 80 per cent of the total flying mileage of the world. Subsidies for aviation last year throughout the world reached the total of £5,000,000, and the output of machines was not less than ten thousand. In the United States civil aviation is of more importance than the military side; in Great Britain 70 per cent of the manufacturing firms depend on Government contracts, but last year 15 per cent of the total products was exported. The future of aviation rests with the development of commercial flying.

GOVERNMENTS are slow to recognise the needs of scientific work, on the western side of the Atlantic as well as on the eastern, and the growth of the U.S. National Museum is a case in point. Started with appropriations from the funds left by an English man of science, James Smithson, the museum owed little to Congress until in 1877 it granted 250,000

dollars for a building. This, now the Arts and Industries Building, was supplemented in 1907 by the New National Museum Building, for which Congress voted 3,500,000 dollars. For long this building has ceased to be adequate housing for the enormous collections, and after much pleading Congress has passed, without a dissenting vote, the Smoot-Elliott Bill authorising an appropriation of 6,500,000 dollars for the enlargement of the U.S. National Museum. The new extension of the Natural History Building will roughly double the present floor space of nine and a half acres, and in addition to increased room for exhibits, this will permit enormous expansions of collections now hopelessly overcrowded. It is interesting to know, as showing an aspect of museum work which does not catch the public eye, and of which even scientific men are sometimes unnecessarily ignorant, that as against 1400 mammals on exhibition in the museum, 210,000 are included in the study collection - a proportion that suggests something of the hidden reserve of research and classification that lies behind the office doors.

WITH the co-operation of the authorities of various national museums, the Museums Association organised a short training course for curators during the week Oct. 6-11. The course was attended by 33 students from provincial museums, for the most part junior assistants, though a few seniors were glad to avail themselves of this opportunity. The gathering was welcomed in the new Conference Hall at the Science Museum by Sir Henry Lyons, when an opening address on first principles of museum work was given by Dr. F. A. Bather, and Dr. E. E. Lowe discussed some fundamental points in museum practice. Succeeding days were devoted to the Victoria and Albert Museum, with demonstrations on textiles, wood furniture, ceramics, prints, and the Circulation Department; the Natural History Museum, with demonstrations on habitat groups, casting of whales, preparing spirit specimens, and preparation of fossils for exhibition; the National Galleries in Trafalgar Square and at Millbank, with talks on storage, cataloguing, and the explanation of pictures; the laboratory of the British Museum, with a lecture on restoration of Egyptian relics.

THOSE who attended this course for museum curators expressed their high appreciation of the arrangements made and of the information imparted. There can be no doubt as to the success of the experiment, and the Museums Association will be encouraged to repeat it. The chief obstacle is the difficulty that members of the staff of provincial museums have in getting leave of absence and in paying the necessary expenses of travel and maintenance; hence the compression into five days of demonstrations that would, with more profit and less weariness, have occupied a fortnight or more. It is to be hoped that the authorities governing museums will see the benefit to themselves of helping the Association over this obstacle, and will not rely entirely on the generosity of individuals or on pecuniary assistance from outside.

THE Council of the British Association has forwarded for the consideration of the Government a resolution urging that effect be given to the recommendations of the Royal Commission on National Museums and Galleries, for the establishment of a National Open-air Folk Museum. The view is expressed that such a museum would best fulfil its objects if established in or quite close to London, and it is further suggested that the possibility might be considered of utilising the gardens of the Royal Botanic Society in Regent's Park for this purpose, in view of their admirable situation and the proximity of a building (St. John's Lodge) suitable for exhibition purposes and offices; provided this can be done without interfering with the use of such part of the gardens as may be available for the scientific work of the Botanical Departments of the University of London.

THE suggestion has recently been made that the swarming of bees is a social expedient due to the need for relief from overcrowding. In the September number of *Discovery* there is a remarkable account of the inducement of artificial swarms amongst termites, which indicates that amongst them climatic conditions may be the stimulus which sets the swarming instinct in motion. Under natural conditions, the swarming of termites takes place at the end of the equatorial summer, that is to say, at the beginning of the rainy season. The Bazinza people, natives of the south-western coast of the Victoria Nyanza, however, can induce swarming at almost any time, in June, July, August, or September, the last being even two months before the normal breaking of the rains. The process, described by R. A. J. Maguire and illustrated by photographs, is an elaborate one. A shelter of leaves is built over a termite mound so that the termitary is in subdued light, suggesting an overcast sky; sticks are beaten to suggest the patter of rain, and water is sprinkled over the 'nest'. Two hours of such activity bring the first winged termites from their galleries, and an hour later the artificial swarm, containing several thousands of 'fertiles', is over. The natives pound these, after the wings have been removed, into a paste which may be eaten raw, but is usually fried and eaten as a flavouring to grain or meat. The artificial swarm raises several biological problems: Is the colony for six months in a condition of overcrowding and awaiting the stimulus of season to break away, or is the stimulus of suitable conditions so strong that it compels swarming whether the termitary is overcrowded or not? Are winged forms specially associated with swarming, or do they exist in the termitary many months before normal swarming takes place? Finally, does the fact that normal swarming at the beginning of the rains may follow artificial swarming in the dry season, mean that between times fresh legions of winged fertiles have been produced to make up the lost numbers?

MARCONI'S Wireless Telegraph Co., Ltd., has built or received orders for many broadcasting stations in Europe; these include three stations in Switzerland, two in Poland, one in Finland, one in Rome and one in the Vatican City, and others at Trieste, Warsaw, and Brno. The Irish Free State has now placed an

order with Marconi's for a sixty kilowatt broadcasting station. When completed it will be one of the most powerful stations in Europe. It will not begin to operate until the autumn of 1931. The waves will be controlled by an oscillating quartz crystal compensated for temperature. This will insure that the frequency of the transmitted waves will be kept constant within very narrow limits. The wave-length used will probably be 413 metres. It is interesting to note that power to operate the station will be supplied from the Shannon high-pressure network. Water-cooled and air-cooled valves will be used in the different amplifier stages. The aerial will be suspended from two lattice steel masts, each 330 ft. in height, and it is at a considerable distance from the transmitting building, in accordance with modern practice. Arrangements have been made to enable the aerial power to be doubled at a later date if required. The alternating current from the Shannon grid will be rectified at the station by a Brown Boveri arc rectifier.

DURING the last eighteen months, progress has been made in building the Battersea generating station. In about two years' time the two huge 80,000 kilowatt generators which have been ordered will begin working. Deptford West, another generating station of the London Power Company, will have a capacity of 195,000 kilowatts. A third large station will be the new Fulham station, the designs for which have been approved by the Central Electricity Board. As these stations will burn thousands of tons of coal daily, the gaseous products of combustion from which will be blown over central London, it is satisfactory to learn from a patent specification, No. 334,660, that Dr. S. L. Pearce, the chief engineer of the London Power Co., and his assistants, are confident that the fumes problem has been overcome. Apparently there is little to fear from grit, dust, and noxious gases when the new stations begin to help the supply of electricity to London. It will not be long before the present stations are working at their maximum capacity, and there will soon be an urgent demand for more electric power. The method Dr. Pearce employs is to cause the products of combustion to pass through a conduit containing a series of spray washing departments. The direction of flow of the gases is altered several times, and they pass through curtains of liquid. The gases are subjected to the action of free iron or other suitable agents so as to convert the sulphur dioxide into sulphur trioxide. A method is also suggested of mixing the gases with ozonised air. Several other claims are made. By the use of hot water and catalysts, the sulphur dioxide, sulphurous acid, and sulphites can be readily converted into substances which can easily be removed.

IN a recent address entitled "Surgery in the Immediate Future", delivered at Guy's Hospital Medical School, and published in the *British Medical Journal* of Oct. 11, Lord Moynihan repeated the assertion for which he had previously been criticised, to the effect that the craft of surgery has now almost reached its limit in respect both of range and of safety. While, however, surgery as a mere mechanical craft can scarcely advance any further, he maintained that it must still continue as a weapon of therapeutics and a weapon of research. He suggested that in the immediate future surgery will concern itself with the sympathetic and parasympathetic nerves in the chest, abdomen and pelvis, intrathoracic diseases, ductless glands, and questions of immunity. He deplored the absence of close affinity between laboratory workers, particularly physiologists, and clinicians, and attributed this defect to a lack of clear vision on the part of both. The new outlook in surgery demands a change in the training of the medical student, which should include a study of logic and philosophy, so as to render his mind more efficient and adaptable. In conclusion, Lord Moynihan criticised the Medical Research Council, which, he says, is too aloof from the day-to-day practitioner of medicine, and out of touch with the desires and needs of clinicians. He holds that the Council should either have a larger representation of clinical medicine and surgery or summon practitioners in an advising capacity.

SCIENCE Service, the well-known American science news agency, has supplied the American press for a considerable time with a regular series of simply written articles on meteorology entitled "Why the Weather?" by Prof. C. F. Talman, the librarian of the United States Weather Bureau. A large number of these have appeared, and continue to appear at frequent intervals, normally as single sheets, each dealing with one particular item of meteorology. The date on which it is intended that the article shall appear is always indicated. This arrangement secures their appearance at a time when the matter under discussion is likely to be of particular interest to the general public. Prof. Talman is to be congratulated on the attractive way in which he writes, and on his unfailing supply of fresh material. With a meteorological library of the size of that of the U.S. Weather Bureau to draw upon, there is no reason why the supply should ever fail, and it is to be hoped that the standard of accuracy set in the early articles can be maintained in the future. In this respect one regrets to see, in a recent contribution entitled 'Buchan Spells', symptoms of a falling off. The impression given in this example is that Alexander Buchan—a sound meteorologist of extraordinary energy, to whom we owe a great debt—was guilty of publishing results of "no scientific value whatever". The fact is that certain writers have attributed ideas to Buchan that the latter almost certainly never entertained, and have made an unjustified practical application of Buchan's results on 'recurrences' of weather to long-period weather forecasting.

THE continued improvement in the maps of the Ordnance Survey of Great Britain in recent years is a matter of general comment. In the Report of the Progress of the Ordnance Survey for 1929-30, the Director indicates some further changes that are proposed. The 1-inch map was originally an engraved map, and the engraved plate formed its basis until within the last few years, when for the 'popular'

edition of the 1-inch map of Scotland drawings reproduced by the helio-zincographic process were used. Drawings are to be used also in the fourth revision of the 1-inch map of England and Wales which has recently been begun. The break with the engraved map will then be complete. Other changes include a more pleasing style of lettering, improved symbols for main roads and railways, the restoration of parish boundaries, and the indication of National Trust areas. The lettered and numbered two-inch reference squares will be abandoned in favour of a grid of 5000 yards side, so that positions can be easily defined by east and north co-ordinates. It is proposed also to incorporate the title, scale, and references as part of the border of the map, instead of leaving them in the blank margins.

The building of large steel frame buildings in cities is often accompanied with so much noise that it becomes very objectionable to dwellers in neighbouring houses. It seems to us that from this point of view alone the new electric welding methods that are coming into use should be welcomed. In the *Westinghouse International Magazine* for August a description is given of the new eleven-story building at East Pittsburgh, U.S.A., which will house the laboratories of the company. The whole of the structural steel framework has been joined up by arc welding without using a single rivet. As 1500 office workers are only a few feet away from the building, considerable annoyance has been avoided. The weight of the framework would have been increased three per cent if rivets had been used. The weather was very inclement when the foundation stone was laid. As this, however, was done in miniature in a reception room several hundred feet away from the actual corner stone which, through a mechanism controlled by photoelectric cells, followed exactly the motion of the model, the heavy rain did not matter. In one of the laboratories in the new building any kind of weather can be imitated so that devices can be tested under the most trying conditions. In another there will be a working model of an electric transmission system supplying a group of towns. There is also a laboratory where artificial lightning can be produced by simply turning a switch. This will be used for practical tests of lightning arresters. The flashes are photographed and analysed by the Norinder oscillograph.

Further developments in the equipment of eastern Canada with water-power are described in *Quebec* for July, in an article on the Beauharnois Canal project on the St. Lawrence river some twenty-five miles above Montreal. From Lake St. Francis on the river above Valleyfield, the new Beauharnois Canal is being cut to Lake St. Louis, a wide portion of the river lower down. The canal will be about fifteen miles long and will carry a quarter of the flow of the river. The fall of 83 feet is to be concentrated at the lower end and is planned to produce 500,000 horse-power, although less than half that amount will be available in two years' time. A 27-foot navigation channel in the canal will be part of the scheme for deep water access to the great lakes. The power will be readily utilised in southern Ontario and Quebec.

A public lecture entitled "Some Biological Aspects of Population" will be given at the London School of Economics and Political Science by Prof. Lancelot Hogben, research professor of social biology in the University of London, on Thursday, Oct. 23, at 5 P.M. The chair will be taken by Mr. H. G. Wells. Admission is free, without ticket. The recent foundation at London of a research chair in social biology is an event of importance to sociology generally, and Prof. Hogben's inaugural address should mark a stage in the study of human society.

Under the Order in Council dated Feb. 6, 1928, the Lord President of the Council has appointed Dr. E. J. Butler, Dr. Kenneth Lee, and Dr. N. V. Sidgwick to be members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research. The following members of the Advisory Council have retired on completion of their terms of office: Prof. V. H. Blackman, Prof. F. G. Donnan, Prof. F. A. Lindemann. The appointment of Sir Ernest Rutherford to be chairman of the Advisory Council, as from Oct. 1, was announced in May last.

The second Henry Herbert Wills Memorial Lecture in physics, founded to commemorate the gift of the laboratory to the University of Bristol, will be given by Prof. J. Franck, of the University of Gottingen, on Saturday morning, Oct. 25, at 11.45, in the Henry Herbert Wills Physical Laboratory of the University of Bristol. The title of Prof. Franck's lecture will be "Relations between Spectroscopy and Chemistry". Visitors from other universities are cordially invited.

The twenty-first Annual Exhibition of Electrical, Optical, and other Physical Apparatus is to be held by the Physical Society and the Optical Society on Jan. 6–8, 1931, at the Imperial College of Science and Technology, South Kensington. As on previous occasions, there will be a Trade Section and a Research and Experimental Section, and the section for the work of apprentices and learners, introduced at the last Exhibition, is to be continued. The Research and Experimental Section will be arranged in three groups: (*a*) exhibits illustrating the results of recent physical research; (*b*) lecture experiments in physics; (*c*) historical exhibits in physics. No charge will be made for space or catalogue entries in the Research and Experimental Section. Offers of exhibits, giving particulars of space and other facilities required, should be communicated, not later than Oct. 30, to the Secretary, Exhibition Committee, 1 Lowther Gardens, Exhibition Road, London, S.W.7.

We much regret that throughout the review entitled "More Antarctic Meteorology" in Nature of Oct. 11, p. 561, the name of the author of the work noticed, Dr. Edward Kidson, was incorrectly spelled Kitson.

A catalogue (No. 14, October) of many secondhand books on botany has been received from Mr. J. H. Knowles, 92 Solon Road, S.W.2. It is one of the fullest recently sent to us.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A handicraft master at the new Metal Work Room of the Bermondsey Central School, with qualifications in metal work—The Education Officer (E.2), County Hall, Westminster Bridge, S.E.1 (Oct. 20). A laboratory assistant at the County and City Mental Hospitals, Gloucester — The Medical Superintendent, County and City Mental Hospitals, Gloucester (Oct. 20). An assistant engineer inspector (mechanical) for service in England under the High Commissioner for India—The Director-General, India Store Department, Belvedere Road, S.E.1 (Oct. 24). Certifying officers under the Ministry of Transport for the various Area Traffic Commissioners' Offices in Great Britain—The Establishment Officer, Ministry of Transport, Whitehall Gardens, S.W.1 (Oct. 24). A whole-time member of the Medical Board for Silicosis—The Industrial Division, Home Office, Whitehall, S.W.1 (Oct. 25). An assistant director of public health (woman), for maternity and child welfare work in the Madras Presidency—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (Oct. 25). A junior engineer under the Safety in Mines Research Board, for research on colliery wire ropes—The Under-Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1 (Oct. 27). A research assistant for physico-chemical work on cellulose at the Manchester College of Technology—The Principal, College of Technology, Manchester (Oct. 31). A research assistant in the University of Leeds for work in connexion with chemotherapy—The Registrar, University, Leeds (Oct. 31). A professor of pathology at the Medical College, Madras—The Secretary to the High Commissioner for India, General Department, India House, Aldwych, W.C.2 (Nov. 3). A technical officer (Grade 1) at the Royal Aircraft Establishment for mathematical work in the application of results of current research to the design of aircraft—The Chief Superintendent, R.A.E., South Farnborough, Hants (quoting A.389) (Nov. 5). An assistant lecturer in physics in the University of Sheffield—The Registrar, University, Sheffield (Nov. 8). A graduate master for biology at the Lord Wandsworth Agricultural College, Long Sutton, Basingstoke—The Principal, Lord Wandsworth Agricultural College, Long Sutton, Basingstoke. A junior botanist at the Rubber Research Institute of Malaya—The Secretary, London Advisory Committee, 2-4 Idol Lane, Eastcheap, E.C.3.

Our Astronomical Column.

Recent Sunspots.—A large group of spots has recently passed across the sun's disc, with the centre of which it was almost coincident on Oct. 11·0. This group, visible for some days to the naked eye, is the largest that has appeared since last December. Its formation was that of a stream or 'bipolar' group, and there were appreciable changes from day to day in the appearance of the component spots. The activity of the group was also clearly evident by spectroscopic observations made at the Royal Observatory, Greenwich, especially between 9^h and 10^h G.M.T. on Oct. 6, when the observed radial movements of hydrogen gas, in the form of dark filaments near the leader spot, were of the order of 150 km./sec. A considerable tract of faculæ (visible in an ordinary telescope when the spots were near the sun's limb) and of bright hydrogen flocculi (seen at all times on the disc with the spectroheliloscope or on spectroheliograms) accompanied the group, mainly in its rearward portion. Brilliant points or small patches of flocculi of a transient nature were also occasionally seen, in particular one that appeared with the formation of the dark filaments described above. The details of the position of the group are as follows:

Date on Disc.	Central Meridian Passage.	Long.	Max. Area.
Oct. 4-17	Oct. 11·0	$7\frac{1}{2}°$ N.	1300 millionths of sun's hemisphere.

Eros.—The errors of the ephemeris of Eros that was published by Prof. G. Witt in vol. 85, No. 9, of *Mon. Not. Roy. Ast. Soc.* in 1925 for the present apparition are proving unexpectedly large. In *Astr. Nach.* No. 5729 he published an improved ephemeris for October 1930; but he now finds that his corrections in this were too small, and *Astr. Nach.* No. 5736 contains an ephemeris by him for November 1930 which has been further corrected with the aid of recent observations. The average correction of the original ephemeris (*Mon. Not. Roy. Ast. Soc.*, vol. 85) for November is $-40^{sec.}$ in R.A., and $+5'$ in declination. It is estimated that it will exceed a minute of time at the time of nearest approach next January. Since the list of comparison stars was drawn up on the basis of the old ephemeris, the error will cause some inconvenience for those who are taking photographs of large scale. Prof. Kobold suggests centring the plate on the old predicted position of the planet, so as to include the selected stars, but some of the observers express a preference for keeping the planet central on the plate, and sacrificing some of the comparison stars. The cause of the error in the ephemeris is not yet located, but as the predicted positions in 1928 were already some 3^{sec} of R.A. in error, there is probably some undetected error in the computations, for an epoch not very long before 1928.

Tempel's Second Periodic Comet. This comet was discovered in 1873 and was found to have the short period of 5 years and 2 months. It has now completed eleven revolutions since its discovery; it was observed in 1873, 1878, 1894, 1899, 1904, 1915, 1920, 1925, 1930. An ephemeris was published in the Handbook of the British Astronomical Association for 1930; with its aid Mr. H. E. Wood detected the comet photographically at the Union Observatory, Johannesburg, on Aug. 26; it was a faint, ill-defined object of the twelfth magnitude.

The following observations are to hand:

Date.	R.A. 1930·0.	S. Decl. 1930·0.	Observer.
Aug. 26·73172 U.T.	$15^h\ 21^m\ 7·20^s$	$11°\ 58'\ 35·6''$	H. E. Wood
,, 28·72106 ,,	15 25 56·28	12 41 16·2	,,
Sept. 22·05471 ,,	16 35 53·6	20 57 15	G. van Biesbroeck

The last observation was made at Yerkes Observatory (*U.A.I. Circ.*, 298).

The following approximate orbit is given in the Handbook:

$$\begin{array}{rl} T & 1930 \text{ Oct. } 5·5 \text{ U.T.} \\ \omega & 186°\ 34'\ 32'' \\ \Omega & 120°\ 52'\ 0'' \\ i & 12°\ 46'\ 33'' \\ \log q & 0·1184 \\ e & 0·5603 \\ \text{Period} & 5·162 \text{ years} \end{array} \left.\begin{array}{l} \\ \\ \\ \\ \end{array}\right\} 1930·0$$

The comet is too far south for convenient observation in England.

Research Items.

Medieval Indian Culture.—In the *Indian Antiquary* for September, Mr. K. de B. Codrington continues his study of the Ajanta frescoes, dealing with ships and boats, horse furniture, arms, metal-working, and pottery. The simplest form of boat is canoe-like and has two masts. It is clearly not a dug-out. Boats used for horse and elephant transport are broad in the beam and have grotesque *makara* figureheads. The large boat of Cave I has a high-pitched and finely cast bow and stern, on both of which *oculi* are painted. The passengers sit under an awning. A merchant ship has a full set of sails with two paddlers amidship. The arms show spears with short triangular blades and ferrules. Daggers are of one type with triangular blades and shaped grip. Three types of shields occur: a small parrying shield of metal; a round shield, usually of hide; and a curved oblong shield with tasselled edges which seems to have been made of black and white bamboo basket-work. Both composite and long bows are found. The swords are of three types: a type comparable with the modern *kukri* with the cutting edge on the incurved side; the long Indian sword with straight pointed blade; the leaf-bladed *pattisā*. All the Ajanta types have survived to-day and the straight and leaf-blade swords are found in Tinnevelly and Nilgiri iron age urn-burials. All have one type of hilt only—an angular V-shaped guard and disc-like pommel. The blade is usually strengthened by processes which run up it either in the middle or along the reverse, necessitated by the peculiar properties of Indian steel, which lacks flexibility. Little can be said of the metal work. Beside lamps and gadrooned pots in Cave I, the only articles recognisable are the mirrors. These are circular with a knob behind, pierced to take a ring or cord. This form is specially associated with China. Mirrors are rare in archæological finds in India, only three being recorded.

Stone Ages in South-east India.—The contents of *Antiquity* for September include a communication by M. C. Burkitt and L. A. Cammiade on palæolithic implements from sites in south-east India situated in the wild country in the Eastern Ghats, which run parallel to the coast for some three hundred miles. The climatic succession which has been worked out for this area may be correlated with the climatic changes now being worked out in East Africa. Four cultures are distinguished, each with its characteristic series of industries. Series 1 is distinguished by the presence of hand-axes made of quartzite which can be closely paralleled by finds from Africa. Thus hand-axes from the Bhaavanasi gravels and from Chodavaram are compared with the gigantic specimen from Nigeria now at Cambridge and examples from Victoria West in South Africa. Series 2 are flake industries with some much more neatly made hand-axes, the material used being chiefly quartzite. Series 3 is characterised by the occurrence of slender blades with blunted backs, a few burins, planing tools, and end-scrapers. This series is best found at sites at the east and west ends of the Nandi-Kanama Pass. Small crescents perhaps link Series 3 with Series 4, a rather monotonous series of microliths with some larger tools. A large number of this series are found on the surface near the Godaveri. They link up with the Wilton of South Africa. The comparative poverty of industries of Series 3 would suggest that we are here on the periphery of the distribution of the Upper Palæolithic found in South, North, and East Africa and extending as far as Transjordania; while Series 4 forms part of the great spread of mesolithic culture.

Education of Cats.—A Chinese psychologist, Zing Yang Kuo, of the University of Chekiang (according to Science Service, of Washington, D.C.), has been testing the reactions of cats to rats and mice. Kittens were isolated at an early age and never knew rats, others were given rats and mice for companions almost from birth, still others were allowed to see their mothers catch and kill rats. Some kittens were brought up as vegetarians, others on a diet of meat and fish. Of the 21 normally educated kittens which watched their parents rat-hunting, 85 per cent killed a rat before reaching the age of four months. Of the 20 kittens kept in a ratless environment, only 45 per cent killed rats without being taught; and of the kittens raised with rats, not one ever killed any of its playmates or any rat of its kind, but 3 of these 18 kittens killed other kinds of rats. The vegetarian kittens were as keen as the others to kill rats, but most of them would not eat the rats they had killed. Indeed, after three to four months of a meatless diet, the vegetarians refused any meat. The experiments indicate that the explanation that a cat hunts by 'instinct' is inadequate, and that the reaction of cat to rat is much more complex and variable than has been supposed. "Our study shows that kittens can be made to kill a rat, to love it, to hate it, to fear it, or to play with it."

Distribution of Birds in the open Atlantic Ocean. During Prof. Johs. Schmidt's *Dana* Expeditions of 1920–22 in the north Atlantic and Gulf of Panama, primarily in pursuit of the breeding area of the fresh-water eel, ornithological observations were made by an experienced worker, P. Jespersen (*Oceanographical Results of the Danish Dana Expeditions, 1920–22*, No. 7, 1930. Copenhagen: Gyldendalske Boghandel; London: Wheldon and Wesley, Ltd., 1930, 6s.). The frequency of the birds observed was greater nearer land, and here fulmars, kittiwakes, skuas, and shearwaters predominated, but birds were seen on the entire stretch across the ocean, the open sea being mainly populated by kittiwakes, skuas, shearwaters, and, particularly in the summer half-year, storm-petrels. Contrary to expectation, the number of birds over the Sargasso Sea was less than elsewhere in the open water, and this scarcity (the German plankton expedition of 1889 saw only one bird in seventeen days) was found to be correlated with a relative scarcity of plankton. The distribution of plankton throughout the whole Atlantic, most abundant near the coasts, least abundant in the Sargasso Sea, appears to determine the presence or otherwise of the sea birds. Thus the Sargasso Sea had fewest birds, but the Gulf Stream area, with its considerably larger quantity of plankton, had a greatly increased number of birds—at least ten times as many per day as in the central part of the Sargasso Sea. In the north-eastern corner of the Atlantic, between Great Britain and Iceland and around the Faroes, the largest quantities of plankton were found, and there was a correspondingly rich bird population.

Manganese in Insects.—Qualitative determinations of manganese in the ash of insects made in the Bio-geochemical Laboratory of the Russian Academy of Sciences by A. P. Vinogradov and M. V. Neustrueva (*Comptes rendus, Acad. Sci.*, No. 6, 1930) proved that it is present in all species (30) examined. The quantity varies from 2×10^{-4} to $1{\cdot}2 \times 10^{-2}$ per cent, the Lepidoptera containing less manganese than any other insects. In the species feeding on green parts of plants, the quantity of manganese is usually higher,

but on the other hand it is very high in some insects with different food—for example, in the mole-cricket (*Gryllotalpa gryllotalpa*, L.) and red ants (*Formica rufa*, L.). In the ants, manganese was found to be concentrated mainly in the abdomen, and it may be suggested that this fact has some relation to the physiology of their poison glands, in connexion with the fermentative oxidation processes taking place there and leading to the production of formic acid. In other insects, there is more manganese in the more active species; this may again depend on more active gaseous metabolism. The influence of manganese on fermentative process in other organisms is well known and its rôle in insects may possibly be the same.

A Lethal Gene in Cattle.—The usual method of breeding cattle, in which bulls are mated to their daughters, tends to bring out recessive genes. No less than eight, and possibly ten, recessive lethal genes have now been found in cattle, compared with eleven in all other mammals. One of these, called short spine, has been described by Mohr and Wriedt (*Jour. Genetics*, vol. 22, No. 2), who discuss the best method for testing the genetical condition of bulls to be used for breeding. The new lethal appeared in the Oplandske mountain cattle of Norway. The anatomical condition of the homozygous lethal is described. The vertebral column and sternum are greatly shortened, as are the neck and thorax; the vertebræ are reduced in number through fusion, and the ribs number six or seven instead of thirteen. The head and legs are normal. These calves die at birth. This condition is exactly complementary to the sub-lethal type called amputated, in which the skeleton of the head and legs is chiefly affected. Both show the same type of inheritance. They must have arisen in the germplasm as mutations. Eleven of the short-spine type have occurred among the descendants of a particular bull. It is not known from elsewhere and may have originated in this bull or his immediate ancestors. As it has not spread far, there should be a good chance of preventing its further spread in the germplasm of other herds, and it may be possible to eliminate it altogether by careful breeding.

Origin of Maize.—The origin of maize, which was widely cultivated by the Indians in North and South America at the time of the discovery of these lands, has long been a subject of hypothesis and investigation. The botanical evidence points to Mexico or Central America as the original home of the plant, but it has never been found wild and must have been greatly altered during the long period of Indian cultivation. It has been generally assumed that the wild plant, whatever its form, was extinct, perhaps even in Aztec times. Mrs. Zelia Nuttall (*Jour. of Heredity*, vol. 21, No. 5) now cites documentary evidence which may lead to a different view. The Chevalier Boturini, an Italian traveller and naturalist, published a work in 1746, after spending eight years in Mexico collecting evidence of its former civilisation. He describes the native tradition concerning the origin of agriculture, that while setting fire to the forests to clear them of wild beasts they noticed grains of maize which had been roasted, and finding them delicious, collected fresh seeds to plant in the soil. Boturini asserts that he himself found in New Spain a maize growing wild in the forests, with a small ear and few seeds, but more delicate in flavour than the cultivated kind. This may have been the wild progenitor of maize, since become extinct through deforestation and other causes. That the plant may still survive in Guatemala is suggested by the experience of Mr. Oliver La Farge, an American, who recently found there, at an attitude of 5000-6000 feet, a wild plant used by the natives in May, when the maize fields had only just been sown. This plant had ears about two inches long, "looking rather like oat-sheaves without the 'whiskers', and having the unmistakable flavour of corn".

Root System of the Tree.—Some results of a very intensive study of the root system of the apple and allied fruit trees are presented by V. A. Kolesnikov in the *Journal of Pomology and Horticultural Science*, vol. 8, No. 3, 1930. The root systems of seedlings and young trees were washed free from soil, studied, and measured. As the result of such laborious work, the author is able to present an interesting picture of the gradual growth of the root system. During the season, branch roots emerge, and then again upon these, branches of a lower order, until, in apples and pears, in a growing season of five or six months, roots of eight orders had appeared. Perhaps as a result, the average length reached by a root is not long and appears to tend to a standard length in a variety. Also, the roots tend to die back from the tip, the branches first formed, which lie nearer the base of any root, dying back first; and therefore the root system, around the base of the trunk, tends to become free of young branches with an absorbing surface still active, whilst further from the trunk a dense array of branching roots, those of younger orders still actively absorbent, are advancing farther into the soil, with a habit of growth which will cause them to 'quarter the ground' thoroughly as they advance.

Dutch Elm Disease in America.—Science Service, of Washington, D.C., reports that the Dutch elm disease, caused by a fungus known as *Graphium ulmi*, which has caused serious damage to elm trees in Holland and has spread into other European countries, has been discovered in Ohio. Three trees in Cleveland and one in Cincinnati have been definitely identified as harbouring the disease and destroyed. A number of other suspected trees in the State are under observation, and State and Federal pathologists are on the look out for new infections. The Dutch elm disease was first observed in Holland soon after the War. Its symptoms are sudden wilting, followed by yellowing and dropping of the leaves. Death of the tree follows, either at once or after a few years of struggle. No cure is known.

Nature of Lake Eyre.—Although Lake Eyre covers about four thousand square miles, little was known of its nature or surface conditions until Mr. C. T. Madigan investigated it, first by air and later by motor-car and on foot, last year. Some of his results are given in a paper in the *Geographical Journal* for September. There is no permanent water and the whole bed is dry at times. Two-thirds of the surface is covered by a salt crust from one inch to seventeen inches in thickness. This crust is 95 per cent common salt with some gypsum and small amounts of calcium, magnesium, and potassium chlorides. Underneath there is a damp gypseous clay to a depth of about eighteen feet, below which is a bed of dolomite. The salt has no seasonal banding, which shows that muddy waters do not flow into the basin. There is no probability that the crust is periodically dissolved. Mr. Madigan notes that the most generous calculation could admit a flooding of only 56 inches a year, against an evaporation of 100 inches. The conclusion, apart from the absence of banding in the salt, is that river floods scarcely affect the lake. Local rain would only affect the first third of an inch of the salt, which is soiled with blown debris. Mr. Madigan favours the theory that the salts date from Upper Tertiary to recent times and are cyclic in origin.

Band Spectra of Tin Monoxide.—In a communication received from Mr. P. C. Mahanti, University College of Science and Technology, Calcutta, it is announced that a number of bands occurring in the spectrum of the tin arc in air, most of them already recorded by Eder and Valenta in the oxy-coal gas flame, have been allocated to three distinct systems. The constants for these have the following approximate values in $cm.^{-1}$:

System *A*	29,631	589	830
,, *B*	23,018	800	1045
,, *C*	22,676	589	800

Further particulars will shortly be published elsewhere.

Forbidden Lines of Neutral Oxygen.—In a short note in the first August number of the *Physical Review*, Dr. I. S. Bowen points out that two weak lines at 6302 A. and 6364 A., which occur in the spectra of certain nebulæ, are almost certainly forbidden lines of the oxygen arc spectrum (O I). An analysis of the ultra-violet arc spectrum of this element has been given by Dr. R. Frerichs in the same issue of this journal, fixing for the first time the value of the low metastable terms from which the auroral green line (5577 A.) arises, and from this it follows that new 'forbidden' lines should occur at 6299 ± 5A. and 6363 ± 5A. It is also mentioned that Prof. Paschen has succeeded in obtaining these lines in the laboratory, and has fixed their wave-lengths accurately at 6300·00 A. and 6363·86 A., so that the assignation of the nebular lines is reasonable. The auroral green line itself has now also been produced from a discharge tube with almost the same isolation as in the spectrum of the night sky, a source having been described by Prof. McLennan and Mr. Ireton in the September number of the *Proceedings of the Royal Society*, which yields only this and λ6965 of argon.

Raman Spectra.—The July issue of the *Indian Journal of Physics* contains a group of eight papers on the Raman effect, which add considerably to our knowledge of infra-red vibrations. The substances which have been investigated include both a number of elements (chlorine, sulphur, carbon, and phosphorus) and some fifty organic and inorganic compounds, chosen mainly in groups which permit of the assignation of more or less definite frequencies to definite radicles. An investigation of the polarisation of Raman lines is described, which shows that there is a close similarity between the polarisation characters of the spectra of compounds of similar structure, and so indicates that polarisation is controlled by the geometry of the oscillations. The utility of the Raman effect in the investigations of physico-chemical properties is also well illustrated by one paper on the influence of polymerisation and molecular association on Raman spectra, with special reference to sulphur trioxide, and by a second on the determination of the characteristic frequency of the diamond by this method; whilst there are numerous good reproductions of the actual spectra from which the measurements have been made.

Anti-fogging Agents in Developers.—Since nearly seventy years ago, many and very various substances have been proposed and added to either the emulsion or the developer to prevent fogging, that is, the deposition of metallic silver during development where the plate has received no exposure to light, and probably a decreasing increase of deposit in other parts. It has been generally supposed that these agents slowed development and so gave time for the denser deposits to increase in opacity before the 'fog' began to show. But P. Wulff patented in Germany several organic bodies for eliminating fog when added to emulsions and claimed that they do not affect the densities of the image. This claim is new, so A. P. H. Trivelli and E. C. Jensen, of the Kodak Research Laboratories (*Jour. Franklin Institute*, p. 287, Sept. 1930), investigated the anti-fogging action of 6-nitrobenziminazole when added to the developer using hydroquinone, pyrogallol, and *p*-aminophenol as developers. They give a large number of curves and tables to show their actual results, and conclude that 6-nitro-benziminazole with these developers is superior to potassium bromide and potassium iodide, giving the least depression of image densities with the same fog-removing quality. With the *p*-aminophenol developer, there was no change of image densities up to 12 minutes development at 20° C. The work is being continued.

Oxidations by Iodic Acid.—Iodic acid has not been much used in organic chemistry, and exclusively in acid solutions. In the September number of the *Journal of the American Chemical Society*, Evans and Dehn show that it can be applied in acid, neutral, and alkaline solutions, and appears to be very selective in its action. The use of iodic acid was shown to lead to improvement in various preparations. A 92 per cent yield of purpurogallin was obtained with sodium iodate and pyrogallol, and benzoin is directly convertible into benzilic acid by the action of sodium iodate in concentrated sodium hydroxide.

Dielectric Polarisations of Normal Paraffins.—In the September number of the *Journal of the American Chemical Society*, Dornte and Smyth describe measurements of the polarisations of normal paraffins from pentane to dodecane over ranges of temperature. The polarisations calculated from the dielectric constants and densities increase about 1 per cent per 100° rise in temperature. The polarisation appears to be an additive property, as would be expected. The values of the electric moments of the molecules are regarded as approximately zero, and the conclusion is drawn that the bonds of alkyl radicals possess no polarity detectable through electric moments arising from them.

Turbulence in Internal Combustion Engines.—The effect of turbulence upon the charge of an internal combustion engine is of great importance, since a stagnant mixture could not be burned in the time available for its combustion in the engine cylinder. In a paper read before Section G (Engineering) of the British Association at Bristol, which appeared in full in *Engineering* for Sept. 5, Messrs. T. F. Hurley and R. Cook attempt to elucidate some points associated with this phenomena; in their efforts to control the condition of turbulence within the engine cylinder they have obtained some interesting data. The paper is in two parts, the first of which deals with experiments when an engine is motored round. In these tests the condition of port entry is varied by means of shaped vanes and the movement of the particles of the incoming charge deduced from photographs of the path of sparks, etc., travelling with the air flow. The second part of the paper presents the results of actual running tests upon the same engine and with the same modifications of inlet port flow, the authors noting the effect upon highest useful compression ratio (H.U.C.R.) of the different conditions of turbulence so set up. It must be borne in mind, however, that the data given refer to only one shape of combustion head, and therefore it would not be wise to generalise from these results. Also, it seems a little difficult and misleading to determine the value of the H.U.C.R. so expressed, when knocking actually occurs at a compression ratio well below the figures given, namely, 5·15 to 1.

Conduction of the Heart-beat.

THE mode of propagation of the wave of contraction in the wall of the heart was thought, up to fifty years ago, to take place along nerve trunks. Gaskell was the first (1882) to show definitely that not only does the heart-beat arise spontaneously in muscle cells but also that the conduction of the excitation from one part of the heart wall to another takes place by muscular tissue. No difficulty was encountered in demonstrating that muscular continuity existed in the case of the lower vertebrates such as the frog and the tortoise. It was generally believed, however, that no such muscular continuity existed between the auricles and ventricles of the mammal; thus, in the human heart, auricle and ventricle on each side were supposed to be united solely by a fibrous ring.

It was not until the year 1892 that Prof. Stanley Kent observed certain muscular bands running from auricle to ventricle which he described in the following terms: "Between the auricle and ventricle and lying in the connective tissue ring are modified muscle cells, usually spindle-shaped, nucleated, granular, becoming extremely narrow in parts and then swelling out again, transversely striated" (*Proc. Jour. Physiol.*, **6**, Nov. 12, 1892). In the following year Kent in Great Britain and His in Germany established the existence of a definite bundle of specialised muscle joining auricle to ventricle. This *A-V* bundle (bundle of His) was further worked out by Tawara (1906), who showed that it had its origin in the *A-V* node of similarly specialised tissue situated at the base of the auricular septum on the right side below and to the right of the coronary sinus. He traced the *A-V* bundle along the top of the interventricular septum just below its membranous part where it divides into the right and left septal divisions; these pass down in each ventricle on the interventricular septum into the papillary muscle arising from the septum. Each half of the bundle gives off several branches which break up more and more, finally forming a reticulated sheet of tissue over the greater part of the ventricles just under the endocardium.

The fibres composing the tissue are distinguished by their primitive character. They are more granular in appearance, due to a higher glycogen content, and consequently appear less striated. The *A-V* bundle forms the only continuous muscular tissue between auricles and ventricles and destruction of it causes complete abolition of the normal sequence of beat between auricles and ventricles. It is now universally accepted that the transmission of excitation in the mammalian heart takes place by means of this muscular bundle.

In 1913 Kent described in the *Journal of Physiology* (*Proc.*) another band of muscular tissue near the auriculo-ventricular groove on the *right* lateral aspect of the heart. In 1914 he demonstrated that this right lateral auriculo-ventricular junction exists in the human heart and establishes connexion between the auricular muscle (right auricle) and the ventricular muscle of the right lateral wall of the heart (right ventricle).

This observation of Kent has either been overlooked or not accepted by other investigators. The division of the well-established auriculo-ventricular bundle (bundle of His) into two to supply both ventricles has adequately accounted for the phenomena observed up to the present in disease and laboratory experiments. Also search by other observers for other conducting paths by the method of combined dissection and serial sectioning has not met with any success; Kent attributes this to the difficulty and tediousness of the task.

In a meeting of Section I (Physiology) of the British Association at Bristol on Sept. 4 last, Prof. Kent brought forward new evidence for the existence of his 'right lateral connexion'. He now backs up the earlier morphological demonstration with experiments on the beating heart proving that the right lateral bundle is a functional entity. If all structures between the auricles and ventricles are severed, leaving only a bridge of tissue between right auricle and ventricle on the *postero-lateral* position, co-ordination persists.

Further, he has found it possible by successive cuts to diminish gradually the breadth of this bridge until it is no more than *one millimetre* across and still co-ordination persists. This co-ordination is of such a kind that the normally occurring contractions of the auricle are followed regularly by contractions of the ventricles, and when spontaneous beats have ceased, artificially excited contractions of the ventricle pass through to the auricle and are followed by auricular beats. Prof. Kent comes to the conclusion that a conducting path exists in this postero-lateral region, which in the absence of the main *A-V* bundle may function in such a way as to maintain the co-ordination of the chambers of the heart.

Meteorology in Agriculture.

AT a time like the present, more than usual interest attaches to any attempts to derive economic advantage from applied science. At the annual paper-reading conference held at the Meteorological Office on Sept. 25 and 26 last under the auspices of the Ministry of Agriculture and Fisheries, all the papers had direct or indirect applications in this direction. The subject of agricultural meteorology is one of those which, through its hybrid nature, is apt to be regarded as the business of neither the meteorologist nor the agriculturist, and it was a recognition of this fact that led to the inauguration a few years ago of the crop-weather scheme and of these annual conferences, where the two classes of investigator can meet and pool the knowledge gained in their special subjects.

Of the five papers read on the first day, the first, by Mr. E. V. Newnham, was mainly meteorological in interest but had an agricultural application in that the subject under discussion—nocturnal radiation from the earth's surface—is one of importance for its bearing upon the damage done to crops by night frosts. A brief summary was given of observations made in this field since Dr. Wells wrote his classical "Essay on Dew", more than a hundred years ago. A qualitative discussion of various factors controlling the temperatures of objects freely exposed to the clear sky at night was followed by a consideration of the desirability of replacing the present form of terrestrial radiation thermometer by an instrument capable of giving quantitative measurements of the heat lost to space in the course of a whole night. Emphasis was laid on the need for further information about the relative powers of common substances for emitting the long-wave radiations appropriate to bodies at low temperatures.

Mr. I. J. Schapringor followed with a paper on the effect of weather on sugar beet. Tracing the effects of weather upon the various stages of cultivation of this crop, it was shown that the equable climate

of England gives us a distinct advantage over Continental countries, where the harvesting of the beet has generally to be completed by the end of October, owing to the probability that frost and snow will intervene if matters are delayed longer. Where this does not happen, harvesting can be spread over a longer period, extending up to Christmas, and the sugar factory can be employed at a moderate pressure of work over a correspondingly lengthened period. The dampness of the climate of England is no obstacle; the fact that our output per acre is about 25 per cent less than on the Continent is explainable largely by the fact that English farmers have not yet discovered the varieties of beet best suited for the climate—a handicap resulting from the seventy extra years of experience in the industry possessed by their rivals abroad.

Mr. J. Hammond showed interesting diagrams illustrating the variation in the proportional size of different parts of Herefordshire cattle at different ages, in the course of a paper on the effects of climatic conditions on animal production. He showed also how variations of weather affect the chemical composition of plants and, through this agency, the character of the growth made by animals feeding on these plants.

The effect of weather on soils was shown by Dr. Ogg to be greater than had at one time been supposed. Owing mainly to the work of certain Russian investigators, modern soil classification is being made on new and much more satisfactory lines than in the past, the principal difference being that formerly the importance of the geological character of the parent rock, the breaking up and transformation of which is responsible for a particular soil, was over-estimated. Wet climates tend to give acid soils and dry climates alkali ones, temperature coming in as a modifying factor. Without any other data than a knowledge of mean temperature and rainfall and of the character of the humus-supplying vegetation, the distribution of the principal types of soil can be roughly mapped out in any country, and work on these lines is being carried out internationally.

In the course of an account of work at Rothamsted Experimental Station on the relationship between the weather of different months and the effectiveness of various artificial manures, Sir John Russell showed the necessity for employing modern mathematical statistical analysis in order to separate the influence of different weather factors. Once this has been done, the result often leaves for solution a comparatively simple relationship that can be explained by chemical experiment in the laboratory. Stress was laid upon the economic importance of a scientific variation of the chemical proportions of artificial manures in accordance with the predominant weather factors for the crop in question, and on the extent to which the application of such a principle can make the yield independent of the meteorological character of the season.

The second day of the conference was occupied mainly with a consideration of the influence of weather upon insect pests. The general impression gained from these papers was that the subject is a harder one to investigate than that of simple plant growth. This arises partly from the fact that many of the pests are of very small size, and the meteorological data available normally do not define exactly the conditions which the pest experiences. There is the added difficulty that the parasites that exercise so large a control over the severity of the attack of a pest are not normally affected in a similar way to their hosts by abnormal weather. Mr. A. Roebuck, who spoke on this subject, showed that where the host and parasite are oppositely affected, great fluctuations of severity of a pest are to be expected; and that, on the other hand, similarity of reaction to weather tends towards limited variation, and therefore to an absence of epidemics. Dr. W. M. Davies described how humidity affects Collembola (springtail): types with a very primitive breathing system are absolutely dependent upon high humidity, whereas those possessing a more advanced tracheal system can withstand relatively dry conditions.

The conference closed with a very interesting account by R. T. Parkhurst of the way in which fowls can be induced to lay as many eggs in the autumn and winter as during the remainder of the year by artificially increasing the hours of light during the dark days, the result being a satisfactory yield at the time when prices are highest. The method is being applied successfully in the United States, especially where cheap electricity is available.

Migration in Butterflies and Moths.*

IT is well known that locusts migrate, but few realise that similar movements take place in other insects, and particularly in the dragonflies and the butterflies and moths. The evidence for such movements is chiefly of two kinds. First, it is found that some insects exist over large areas only for a short time, and after a period of absence may appear again suddenly in large numbers. Secondly, observers, particularly but by no means entirely in the tropics, have often seen hundreds of thousands of butterflies moving steadily in one direction, sometimes passing for hours on end and sometimes even for days or weeks.

By collecting such evidence it has been possible to get an idea of the regular movement made by some species. Thus the Monarch or Milkweed butterfly of North America is found during the summer throughout the greater part of the continent, even reaching so far north as Hudson Bay. In the autumn all the individuals in the north collect together in great bands and fly a thousand or so miles south to the Gulf States or Southern California, where they spend the winter clinging in masses to trees. In the spring the bands break up and the butterflies fly north, laying eggs as they go, to repopulate the whole area—some completing another thousand or fifteen hundred miles flight on the return journey.

In West Africa, Europe, and western Asia, the greatest migrant is the Painted Lady butterfly, which in the spring crosses the Sahara and Egyptian deserts from some almost unknown sources to the south; crosses the Mediterranean, often in hundreds of thousands; flies more or less northward through Europe, usually reaching the shores of Great Britain in early June, and sometimes individual stragglers are seen in the extreme north of Iceland or within a few degrees of the Arctic Circle. The total distance covered by these flights may be between two and three thousand miles, but at present it is not possible to say with certainty if any one individual flies the whole distance or if it is covered by two successive generations. The butterflies lay eggs as they go and in England a local-bred generation may result in August or September, but there is practically no evidence of the survival of this butterfly in north and central Europe from one year to the next. Another remark-

* Substance of a paper read by Mr. C. B. Williams before Section D (Zoology) of the British Association at Bristol on Sept. 8.

able fact is that there is at present little or no evidence of any return movement towards the south in the autumn.

The common Large Cabbage White butterfly is also a migrant, particularly in central Europe, where about July large swarms seem to originate either in Scandinavia or on islands in the Baltic, and fly southward through Germany in clouds like snowstorms. Some of these flights deviate to the west and may cross the North Sea and appear on the eastern shores of Great Britain.

Similar flights occur in all parts of the world: West Africa, East Africa, South Africa, India, Ceylon, Central and South America, and Australia, all have their migrant butterflies. The sight of hundreds of thousands of butterflies passing a point steadily in a fixed direction day after day is one never to be forgotten. Mr. Williams stated that in East Africa he has seen a 'skipper' butterfly flying to the south on every fine day for more than six weeks, in numbers which reached a maximum of more than five hundred per minute on a 22 yards front. On another occasion at the same station there were simultaneous flights of two different species of butterflies going on in exactly opposite directions for nearly a month, each species keeping strictly to its predetermined path. Further, on one day while these two flights were going on, there was a third flight of millions of locusts moving diagonally across the other flights and not in any way interfering with them.

Nothing is yet known of the reasons for these movements or of the factors which determine the direction of flight. It can, however, be stated quite definitely that the insects are *not* blown by the wind. Examination of a large number of records show that the flights are as often directly against the wind as with it, and may cross it any angle.

Butterflies in migration appear to have an urge to fly continuously in one fixed direction; they appear to be conscious of that direction and make every effort to keep to it in spite of the disturbance due to wind and the presence of obstacles in their path. They usually avoid small obstacles by flying over them, or more rarely round them, but have been seen beating themselves against the wall of a house or entering open windows. Efforts to keep to the desired path have often been observed, and they have been recorded as flying through railway tunnels or in at one side and out at the other of partly constructed buildings, rather than depart from it.

Similar movements occur in many species of moths, but information about them is much more difficult to obtain, owing to the fact that the majority of these migrations take place at night.

Fishing Methods of the Maori.*

THERE appears hitherto to have been little information placed on record concerning Maori fishing methods and devices. Mr. Elsdon Best's monograph, in which every aspect of Maori fishing activity is clearly and fully described, is therefore a welcome addition to the scanty literature which already exists.

Fishing operations in all the countries of the world have connected with them many strange beliefs, weird superstitions, and quaint ceremonies to celebrate special occasions such as the launching of a new boat or the first dip of a new net. Fishing in Maoriland was no exception to the rule, and many strange and interesting rites and usages connected with the craft are described. Many of these have their counterpart in other lands; a few seem to be peculiar to the Maori.

Sea fishing was considered by the Maori to be essentially a task for men. The boats, however, were almost invariably met by the women, to whom the entire subsequent care of the catch was left. Women also were expected to collect shellfish and allowed to take part in the capture of small fresh-water fish, but eel-fishing was confined entirely to men.

The most useful and interesting part of the bulletin is the section dealing with fishing implements, their manufacture and use. Where the conditions were suitable, nets of various kinds were mainly used, chief among them being a kind of giant seine which might be anything up to 1000 yards in length. The making of such a net, the material of which was unscraped flax, was the work of all the inhabitants of a village and was made use of to benefit all the part proprietors of it. These nets were five to six feet in depth, provided with sinkers along the bottom and floats of very light wood (instead of the usual cork) along the top. A point of unusual interest about these seines and the other nets of the Maori is that so far back as can be traced, the knots used for making the meshes were exactly the same as those of our own European nets. How this knot came to be discovered and adopted in net making by peoples and tribes all over the world amongst whom intercommunication must have been impossible is a riddle yet to be explained.

In addition to the great seines, many smaller nets were employed, including drag nets and set nets, but no mention is made of drift nets. These do not appear to have been used in Maoriland. Line fishing also was largely practised, especially along rocky coastlines where drag-nets could not be employed. Wood, bone, stone, and shells were all used by the Maori in the manufacture of fish hooks. When Europeans arrived in the country, however, the natives soon learned the advantages of metal for the making of such implements.

The bulletin is attractively produced and well illustrated, but appears to suffer slightly from the fact that the author, apart from his researches in producing this work, seems previously to have had little intimate contact with fishermen and fisheries.

* Fishing Methods and Devices of the Maori. By Elsdon Best. Dominion Museum Bulletin No. 12. 1929. Dominion Museum, Wellington, New Zealand. Also obtainable from New Zealand Government Offices, 415 Strand, London, W.C.2. Price: Paper Cover, 9s.; Cloth Cover, 11s. 6d.

Recent Work on Buttercups.

AT the present time considerable attention is being paid to these familiar wild flowers, comprising the genus *Ranunculus*, the largest one in that attractive family the Ranunculaceæ. Parkin has in recent years (*Annals of Botany* 42; 1928) emphasised the fact that in this genus two distinct types of petal occur—one yellow and *glossy*, typical of the common buttercups of our fields and meadows; and the other white (occasionally yellow or even red), with a *mat* surface, exemplified only in Great Britain by the water buttercups (Batrachium section). The former type of petal is probably unique among flowers, possessing peculiar structural features, one of which is the large amount of starch contained in it and restricted to the part that is glossy. It is suggested that this large genus might be conveniently and perhaps

also phylogenetically divided into two sub-genera—one containing the glossy and the other the mat petalled species.

Marsden-Jones and Turrill are collaborating in a genetical study of this genus, and last year they published a preliminary account of their results with the two common buttercups, *Ranunculus acris* and *R. bulbosus* (*Jour. of Genetics*, **21**, abstract in NATURE, **124**, p. 928). One of the most interesting points connected with these species is the occurrence of plants functionally only female. Reference to these was made in the correspondence columns of NATURE last year (**123**, pp. 568, 798, and 911).

A Japanese botanist, M. Kumazawa, has this year published the results of his morphological and anatomical study of the species of *Ranunculus* occurring in his own country (*Jour. Faculty of Science*, Univ. Tokyo, Botany 2, pt. 3). The island empire of Japan is sometimes regarded as the eastern counterpart of the British kingdom, and in keeping with this it so happens that the number of species (sixteen) found there is about equal to the number usually recognised in Britain. Furthermore, as in the British flora, the only species that have not yellow and glossy petals are white water buttercups.

Two endemic species present interesting vegetative features. *Ranunculus Zuccarini* has root tubers suggestive of those of the Lesser Celandine (*R. Ficaria*). *Ranunculus flagellifolius* has filiform leaves monocotyledonous in appearance. Evidence is brought forward to show that these foliar organs have evolved through the transformation of the whole of an ordinary leaf and are not merely modified leaf stalks (phyllodes).

The main part of the paper is taken up with vascular anatomy. Interesting points in connexion with the endodermis are described. There is a marked tendency in the stem to closed bundles of the monocotyledonous type.

From the morphological and anatomical point of view *Ranunculus sceleratus*, a widely distributed species and fairly common in Britain, is regarded probably as one of the most primitive members of the genus.

Autumn-sown Cereals.

THE choice of a good variety of cereal may make a difference of more than twenty per cent in a farmer's returns, and yet the crop will cost him no more to grow. For this reason the National Institute of Agricultural Botany, Cambridge, has issued a number of recommendations, based on careful trials at a number of stations, as to varieties of cereals suitable for autumn sowing. These do not necessarily apply to the north of England, but may be accepted with confidence in other districts.

The reaction of different varieties of wheat to diseases such as foot-rot or whiteheads is as yet far from complete, but there is no reason to believe that any one variety is markedly more resistant or susceptible to them than another. As regards winter hardiness, it should be borne in mind that other factors besides frost resistance are important in England, and that on the whole, Scandinavian and Dutch wheats are less adapted to our conditions than such a variety as *Squarehead's Master*. The value of change of seed is still a vexed question, but there seems no evidence (given equal purity and germination) that foreign-grown seed is preferable to stocks of the same variety grown in England.

Wilhelmina or *Victor* are the most trustworthy high-yielding varieties on soils in good condition; *Yeoman* or *Yeoman II* possess unique bread-making quality and are the varieties to grow on the richest soils or under intensive manuring; *Little Joss* should be chosen for the lighter wheat soils, particularly in Norfolk, or where fertility is low; *Iron III*, though less trustworthy than *Wilhelmina* and apt to develop rust, like *Weibull's Standard*, finds a place on heavy soils. *Rivett*, or *Blue Cone*, probably outyields all other varieties on heavy soils in the south of England, and *Squarehead's Master* stands by itself in its adaptability to all sorts of conditions and the regularity with which it gives a certain crop.

Grey Winter is the only really trustworthy variety of oats, but its weak straw is a serious disadvantage. If strength of straw is an essential point, black-grained *Bountiful* is suggested. There is no winter-hardy white oat on the market. As regards barley, the ordinary six-row winter variety gives a satisfactory crop, but the grain is not of malting quality. However, although none of the malting barleys are winter-hardy, *Plumage Archer* and *Spratt Archer* can usually be grown successfully, if exposed situations and badly drained soil are avoided, and when autumn-sown, outyield similar spring-sown crops. Anyone wishing for fuller particulars is advised to write to the National Institute of Agricultural Botany at Cambridge.

University and Educational Intelligence.

BIRMINGHAM.—The celebration of the jubilee of Mason College and the thirtieth anniversary of the granting of a charter to the University commenced on Oct. 13. The Chancellor, the Viscount Cecil of Chelwood, in the course of his address, referred to the foundation in 1880, by Sir Josiah Mason, of Mason College as a college of science and technical knowledge for Birmingham, at a cost of £200,000. The College became the University in 1900, and the first principal was Sir Oliver Lodge, who was present at the celebrations. The honorary degree of doctor of laws was conferred on the following, among others: Sir Henry Hadow, Sir William Hardy, Sir Thomas Lewis, and Dr. F. E. Smith.

CAMBRIDGE.—At Trinity College, J. W. Brunyate, L. H. Gray, and R. E. A. C. Paley have been elected to fellowships. At Corpus Christi College, Dr. G. S. Carter, formerly lecturer in zoology in the University of Glasgow, has been elected to a fellowship.

The John Winbolt Prize has been awarded to S. Steele, of Christ's College, for a dissertation on "Chemical Changes in Fuel-air Mixtures in an Internal Combustion Engine during Compression".

LONDON.—Two courses of advanced lectures have been arranged in the Faculty of Engineering at King's College. Mr. T. G. Rose is giving three lectures on "Management", on Tuesdays, beginning Oct. 21; and Col. C. H. Bressey, Chief Engineer, Roads Department, Ministry of Transport, will deliver three lectures on "Modern Road Construction", on Tuesdays, beginning Nov. 11. Particulars can be obtained from the College.

MANCHESTER.—The Council has accepted with regret the resignation of Prof. O. T. Jones, who has held the chair of geology and the directorship of the Geological Laboratories since 1919. Prof. Jones has been elected to the Woodwardian chair of geology in the University of Cambridge, and will vacate his Manchester appointment in December. The Council has also accepted the resignations of Dr. John Walton, senior lecturer in botany, who has been elected to the Regius chair of botany in the University of Glasgow, and of Mr. L. J. F. Brimble, lecturer in botany.

Dr. J. H. Frazer (Johns Hopkins) has been appointed lecturer in mathematical physics.

ST. ANDREWS.—At the graduation ceremonial on Oct. 10, the honorary degree of LL.D. was conferred upon J. A. C. Kynoch, emeritus professor of midwifery, University College, Dundee.

APPLICATIONS are invited by the Zoological Society of London for an aquarium research fellowship for three years, of the annual value of £350. The successful applicant will be expected to do research in connexion with aquatic life, principally in the laboratory attached to the Society's aquarium, under the general advice of some naturalist appointed by the committee, and to report quarterly to the committee on the progress of the research. Applications should be addressed to Sir Peter Chalmers Mitchell, Zoological Society, Regent's Park, N.W.8, and received on or before Nov. 3.

AN arrangement has existed for the past six years whereby, when a candidate for a Higher National Certificate in Mechanical Engineering at the termination of an advanced course includes a specialised automobile engineering subject in his final examination, the signature of the president of the Institution of Automobile Engineers can be added to any certificate awarded. This arrangement has now been extended to ordinary certificates awarded at the termination of senior part-time courses. Applications should be addressed in the first instance to the Board of Education.

THE following research fellowships are open to members of the British Federation of University Women: A Senior International Fellowship (offered by the International Federation of University Women), value £250; an American International Fellowship (offered by the American Association of University Women), value approximately £300; a Caroline Spurgeon International Scholarship in Arts (offered by the Directors of the Crosby Hall Association), value £100 a year for two years; an International Residential Scholarship at Crosby Hall (offered by the British Federation of University Women), value £100; and a German International Fellowship (offered by the German Federation of University Women), value approximately £100. Application forms and regulations are obtainable from the Secretary, British Federation of University Women, Crosby Hall, Cheyne Walk, S.W.3.

FOR the tenth year in succession, Trinity College, Cambridge, announces the offer of a Research Studentship open to graduates of other universities who propose to go to Cambridge in October next as candidates for the degree of Ph.D. The value of the Studentship may be as much as £300 a year if the pecuniary circumstances of the successful candidate require so large a sum. Applications must reach the Senior Tutor not later than July 1, 1931. The same College offers, as usual, Dominion and Colonial Exhibitions to students of Dominion and Colonial universities. These Exhibitions are of the titular value of £40, but their actual value is such sum (if any) not exceeding the titular value as the College Council may from time to time hold to be justified by the exhibitioner's financial circumstances, and the Council has power, if it sees fit and if funds are available, to award an additional payment. Candidates must apply through the principal authority of their university, and applications should reach the Senior Tutor (from whom further particulars may be obtained) by July 1, 1931.

Historic Natural Events.

Oct. 19, 1800. Hailstorm in Bedfordshire.—During a violent thunderstorm in Bedfordshire, hailstones fell, shaped like oblate spheroids, six to nine inches in circumference.

Oct. 19, 1917. Unexpected Upper Winds.—A fleet of thirteen Zeppelin airships attacked London on Oct. 19 in weather conditions which appeared settled. Owing to the unexpected development of a barometric depression, however, a very strong cold north-east wind sprang up at some height above the ground. Fog and cloud prevented the raiders from determining their position, and they were carried southward over France, where they were discovered. The motors being handicapped by the intense cold, the greater part of the Zeppelin fleet was destroyed.

Oct. 20, 1743. Hurricane at Port Royal.—A furious hurricane began at 6 P.M. at Port Royal, Jamaica. Many houses were blown down, but most of the damage was done by the sea, which rose many feet and destroyed all the wharves, while the streets were several feet under water. Out of 105 ships in the harbour only one rode out the storm, and a great number of marines were drowned. The hurricane was followed by a pestilence which caused still greater loss of life.

Oct. 22-25, 1805. Trafalgar Gales.—After the battle of Trafalgar violent south-westerly gales blew on the south-west coast of Spain, and it proved impossible to get the majority of the captured French and Spanish ships into Gibraltar.

Oct. 23-24, 1924. Typhoon off Coast of Annam.—A typhoon of exceptional violence, accompanied by torrential rains and a storm wave, travelled along the coast of Annam, causing floods, loss of harvests, and great damage to buildings, roads, bridges, railways, and telegraph lines. The regions which suffered most were the provinces of Kinhoa and Song Ba.

Oct. 24, 1847. Aurora Borealis. A brilliant display was observed from London on the night of Oct. 24-25. As described by J. Glaisher, it began with a bright red streamer in the north-west at 6.30 P.M., but was not well developed until 9.55 P.M., when a pyramid of red and orange light appeared in the north-west, 5° in diameter at the base, and resembling the glow from an immense conflagration. At 10 P.M. this had become deep crimson, and a similar one had formed to the east-north-east, these two pyramids forming the boundaries of a fan-shaped mass of vibrating silvery columns converging to a point a few degrees south of the zenith. About 10.20 P.M. the moon, which had been shining from a cloudless sky, was suddenly surrounded for a few minutes by a fine corona, with concentric circles of grey, violet, green, and red. Soon after 11.15 a bright arch appeared extending from north-west to south-east, with flickering streamers both above it and below it. This continued until 1 A.M. There were magnetic disturbances at Greenwich on Oct. 22 and 24.

Oct. 25, 1665. Gale in London.—There was a violent gale in London with much rain. It is stated in the *Philosophical Transactions* that during this storm the barometer stood at 28½ in., and that on the evening of Oct. 26 it descended nearly to 27½ in.

Oct. 25, 1859. ***Royal Charter*** **Storm.** During a terrible storm the *Royal Charter* was wrecked on the coast of Anglesea, with the loss of nearly five hundred lives. This disaster led directly to the establishment of a meteorological service in England and to the issue of gale warnings by Admiral FitzRoy. In the same storm the *Great Eastern* narrowly escaped destruction at Holyhead, while Stephenson's viaduct at Penmaenmawr was carried away, the old Chain Pier at Brighton was destroyed, and great damage was done to the railway on the beach below the cliffs at Dover.

Societies and Academies.

PARIS.

Academy of Sciences, Sept. 8.—W. Vernadsky: The radium in aquatic organisms. The amounts of radium in different species of *Lemna* growing in lakes containing known amounts of radium have been determined. The concentration of radium in the living plant is 100-650 times that present in the water. The amounts of radium vary considerably with the species of *Lemna*, and this variation does not depend on the weight of the individual plant. The question as to what is the function of radium in the vital processes of *Lemna* still remains unanswered.—**Auguste Lumière** and **Mme. R. H. Grange**: The protective action of cholesterol against shock caused by floculates. The facts cited prove that injections of cholesterol protect the animal (rabbit) against shocks of the anaphylactic type. **Joergen Rybner**: Nomograms for transformations between rectangular and polar co-ordinates and for complex hyperbolic functions. **Cl. Chevalley**: The theory of normic residues. **Radu Badesco**: Logarithmic solutions of an integral equation.—**Luca Teodoriu**: A partial differential equation which occurs in the problem of average.—**F. Charles** and **J. Flandrin**: Contribution to the study of Cretaceous soils in the north of Anatolia (Asia Minor).—**P. Fallot, A. Marin,** and **M. Blumenthal**: The limestone chain of the Spanish Rif between Xauen and oued M'ter.—**Th. Biéler-Chatelan**: The polysynthetic quaternary glacier of Monti Simbruini (Central Apennines). The causes of its extension. The author concludes that in the Apennines, in spite of the altitudes being lower than the Alps, the quaternary glaciers could have reached dimensions comparable with those of Alpine glaciers, this being due to the heavy rainfall which has always characterised these ranges. **Jules Amar**: The diaphragm origin of respiration. **Angelo Migliavacca**: The lipochrome interstitial cells of the uterus.—**Rémy Collin** and **Pierre Florentin**: The growth of the nuclei in geometrical progression in Lœwenthal's gland.—**Mme. Y. Khouvine, E. Aubel,** and **L. Chevillard**: The mechanism of the transformation of pyruvic acid into lactic acid in the liver.

GENEVA.

Society of Physics and Natural History, July 3.—H. Decker: System of organic combinations. The author has constructed curves permitting the prediction of the possible combinations; carbon and hydrogen are plotted on rectangular co-ordinates. For the more complex combinations, he combines several networks with a parallelogram mesh, such that all possible combinations find their place at the nodes of a parallelopiped mesh.—**R. Cherbuliez** and **G. de Mandrot**: The disaggregation of casein in acetamide. By heating casein in acetamide a true depolymerisation of the casein can be brought about without the chemical intervention of a foreign substance. This depolymerisation is accompanied by a profound modification of the original molecular edifice, but does not destroy the groupings which give on hydrolysis the amino-acids characteristic of the original proteid.—**A. Georg**: The determination of the constitution of the disaccharides by the method of methylation and its application to Fischer's isomaltose. By this method, the author deduces two possible constitutions for isomaltose; either that of a 6-α-glucoside (1·5)-glucose (1·5) or that of a 5-glucoside (1·5)-glucose (1·5). The first appears to be the more probable.—**Eugene Pittard** and **Juan Comas**: The condylo-diaphysary angle (angle of divergence) of the femurs of Bushmen, Hottentots, and Griquas. The authors find differences between the averages for the two sexes and others between the right and left sides. These differences are not the same in the Hottentots and the Griquas; granted a common origin, these differences may perhaps be attributed to the mode of life.

LENINGRAD.

Academy of Sciences (*Comptes rendus*, No. 1, 1930).—**F. Loewinson-Lessing**: A contribution to the petrography of Kamtchatka. Analyses of a series of specimens of lavas from Kamtchatka are given; most of the lavas are characterised by the presence of basic plagioclase phenocrysts, of basaltic hornblende, and by vitrophyric texture; lavas containing pyroxene are rare.—**I. Vinogradov**: The least primary root.—**I. Medvedev**: The problem of bios. The question as to whether yeast cells can develop in an artificial medium, without living elements in it, has been decided by various authors differently. This difference is due to neglecting the possible osmosis of physiologically active substances (bios) from the yeast cells themselves into the medium. Removing the substances so diffused by quick washing proved that they play a very important part in the development of yeast in an artificial medium.—**N. Dneprovsky**: The fundamental systems of the declination of stars.

Comptes rendus (No. 2, 1930). **A. Tchitchibabin**: (1) Non-tanning substances in the extract from the rhizome of *Saxifraga* (*Bergenia*) *crassifolia*. (2) Arbutine. Both the rhizome and the leaves of *S. crassifolia* contain up to 10 per cent of the dry weight of the glucoside arbutine, which has so far been known only in the plants of the family Ericaceae and in *Pyrola*.—(2) Non-tanning substances of *Statice*: (1) Myricetine. A species of *Statice* from Turkestan was found to contain up to 1 per cent of the glucoside myricetine.—**A. Tchitchibabin** and **N. A. Preobrazhenskii**: The synthesis of the pylopic acids and the structure of the pylocarpine.—**N. N. Jakovlev**: (1) The genus *Petschoracrinus* and the transition from the dicyclic crinoids to the monocyclic ones. A series of specimens of *Petschoracrinus* exhibited a complete transition from the monocyclic to the dicyclic type, and the use of this character for the separation of the two sub-classes appears not to be justified.—(2) The primary pores of *Cystoblastus*. The madreporite of *C. kokeni* is kidney-shaped, perforated, and placed over the three interradial plates. On the concave side of the madreporite there is an orifice which must represent the gonopore. **E. Perepelkin**: (1) The alteration of the rotation of the sun with the height. Prominences in different layers of the sun's atmosphere rotate with the same velocity.—(2) The separation of velocities of different gases in the prominences.

J. Medvedev: The theory of the simultaneous action of the external factors on the yield of crops. A method is offered for the calculation of the optimum combination of factors.

ROME.

Royal National Academy of the Lincei, May 4.—E. Paternò: The origins of stereochemistry. So long ago as 1869, Paternò proved the existence of two isomeric compounds of the formula C_2HCl_5 and attempted to explain their isomerism by means of spacial structural formulæ.—**F. Zambonini** and **Silvia Restaino**: Double sulphates of rare earth and alkali metals (13). Sulphates of praseodymium and ammonium. In addition to the compound, $Pr_2(SO_4)_3$, $(NH_4)_2SO_4$, $8H_2O$, described by von Scheele in 1898,

these sulphates form the anhydrous double compound, $Pr_2(SO_4)_3, 5(NH_4)_2SO_4$, which is stable at 25° in contact with solutions containing from 63 to 56 per cent of ammonium sulphate and from 0·2 to 0·6 per cent of the praseodymium salt. The crystallographic characters of this double salt are described.—**S. Franchi**: The non-existence of the 'nappe de l'Embrunais' in Italian territory, indicated to the south of Mont Blanc in a geological map by Léon Moret.—**F. Zambonini** and **A. Ferrari**: The identity in crystalline structure of the cancrinite of Monte Somma with that of Mias. The recent and most satisfactory analyses of cancrinite indicate the formula, $3(Na_2, Ca)Al_2Si_2O_8(Na_2, Ca)CO_3$, with a slight excess of carbonates and a variable proportion of water.—**Giulio Bemporad**: The significance of the principle of the arithmetic mean. **R. Caccioppoli**: A general theorem on the existence of unit elements in a functional transformation. **M. Brelot**: The integrals of $(1)\Delta u - c(M)u(M)$ $(c \geq o)$ in the neighbourhood of a singular point 0 of $c(M)$. **Enrico Volterra**: The deformation of an elastic medium due to a small displacement of an immersed rigid sphere.—**B. Caldonazzo**: Plane irrotational motions of perfect liquids in the presence of a movable disc. **A. Consiglio**: A further exception to the Kutta-Joukowski theorem. The case of Joukowski's pisciform obstacle, with a single cuspidal point, is considered.—**Luisa Pelosi**: A new demonstration of a theorem of Painlevé-Levi-Civita on dynamic equations.—**Anna Eredia**: The coefficient of persistence of rainy days. The probability of the occurrence of rainy days, singly or in groups, was studied for Hamburg (1876-1900) by Grossmann, who, on the assumption that the various groupings were equally probable, derived formulæ for calculating the mean number of rainy days out of two, three, or more consecutive days. The values so calculated did not, however, agree with observations made over a considerable number of years, a result which was recently confirmed by Besson in the case of Paris, and by Domingo y Quilez in that of Saragossa. For Rome, the author finds that the coefficient of persistence of rain varies throughout the year, the maximum being in March and the minimum in July. The coefficient of probability of rain increases with increase in the preceding number of wet days, up to five in the case of Saragossa and to four in that of Rome.—**E. Segrè**: Intensity of the lines in the Raman effects of diatomic molecules. The quantum mechanical formula for the intensity of the Raman lines for the molecule O_2 is explained and is found to furnish results in good agreement with the experimental values.—**B. Rossi**: The action of the counter tube of Geiger and Muller.—**G. Racah**: An example of the quantistic treatment of an interference phenomenon. **A. Ostrogovich**: Investigations on γ-triazines: synthesis of phenylaminohydroxytriazine. This compound may be synthesised by the interaction of benzamidine hydrochloride on guanylcarbamide acetate, and it seems likely that other aminohydroxytriazines may be similarly obtained.—**A. Debenedetti**: The determination of plagioclases by measurement of the angles of extinction in the zone normal to (010).—**Giulio Cotronei** and **Aldo Spirito**: Zoological constitution and grafting (3). New experiments on Anura and Urodeles.—**M. Comel**: Studies on parathyreoprive syndrome (2). Preventive action of irradiated ergosterol in excessive doses.

SYDNEY.

Linnean Society of New South Wales, July 30.—**J. R. Malloch**: Notes on Australian Diptera (25). This paper contains (*a*) additional notes on Ortalidæ, Sapromyzidæ, Clusioididæ, and Neottiphilidæ, (*b*) a revision of the Calliphorid subfamily Metopiinæ, and (*c*) some notes on Empididæ, with a key to the subfamilies. Thirty species are dealt with, fifteen of which are described as new. Three genera of Metopiinæ are also described as new. Keys are given for separation of the genera of Metopiinæ and species of *Tapeigaster*, *Miltogramma*, and *Protomiltogramma*.—**Rev. H. M. R. Rupp**: Notes on the autumn orchids of the South Maitland coalfields. Notes on nine species of *Pterostylis* and *Acianthus exsertus*. One species of *Pterostylis* is described as new.—**A. A. Lawson**: The origin of endemism in the angiosperm flora of Australia. This paper gives the author's observations on the sterility of various members of the Proteaceæ and Myrtaceæ. The percentage sterility of the pollen is very high in some types, amounting to as much as 95 per cent. The pollen sterility is generally associated with low seed-output. The view is expressed that the sterility of the pollen is the result of natural hybridisation.

Diary of Societies.

FRIDAY, OCTOBER 17.

INSTITUTION OF MUNICIPAL AND COUNTY ENGINEERS (North-Western District) (at Liverpool), at 2.

PHYSICAL SOCIETY (at Imperial College of Science), at 5.—J. P. Andrews: (a) A Simple Approximate Theory of the Pressure between Two Bodies in Contact; (b) Experiments on Impact; (c) Observations on Percussion Figures.—Dr. R. Hase: Some Physical Radiometric Investigations of Technical Interest.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—L. St. L. Pendred: Presidential Address.

SOCIETY OF DYERS AND COLOURISTS (Manchester Section) (at 36 George Street, Manchester), at 7.—F. Scholefield: Chairman's Address.

SOCIETY OF CHEMICAL INDUSTRY (South Wales Section) (jointly with Institute of Chemistry) (at Thomas' Café, Swansea), at 7.—E. E. Ayling: Some Applications of the Electronic Theory in Organic Chemistry.

IRON AND STEEL INSTITUTE (Glasgow Section, jointly with West of Scotland Iron and Steel Institute) (at Royal Technical College, Glasgow), at 7.15.—R. Hamilton: Presidential Address.—Discussion on papers by H. C. Wood: Open-hearth Furnace Steelworks: a Comparison of British and Continental Installations and Practice; and J. Šárek: What Reasons compelled the Prague Ironworks to Introduce Thin-walled Blast-furnaces.

BRITISH ELECTRICAL DEVELOPMENT ASSOCIATION (at Royal Society of Arts), at 7.30.—Lt.-Col. W. A. Vignoles: An American Tour and Experiences.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—T. H. Flowers: The London Automatic Telephone System.

ROYAL SOCIETY OF MEDICINE (Obstetrics Section), at 8.—Dr. G. I. Strachan: Vaginal Metastases in Uterine Carcinoma. Dr. W. H. F. Oxley: The Organisation and Methods of Practice of the East-End Maternity Hospital.

ROYAL SOCIETY OF MEDICINE (Electro-Therapeutics Section), at 8.30.—Prof. J. M. W. Morison: Radiology—its Progress and Future (Presidential Address).

MONDAY, OCTOBER 20.

BRITISH PSYCHOLOGICAL SOCIETY (Education Section) (at London Day Training College), at 6.—Dr. Barbara Dale: An Investigation on the Use of Intelligence Tests with University Students.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Section, London), at 6.45.—A. E. Hamblin: Mass Production of Tin Containers.

INSTITUTION OF ELECTRICAL ENGINEERS (Mersey and North Wales (Liverpool) Centre) (at Liverpool University), at 7.—A. J. Pratt: The Development of the Telephone System.

HUNTERIAN SOCIETY OF LONDON (at Simpson's Restaurant, Cheapside), at 7.15.—Prof. A. W. Sheen: The School of Health (Presidential Address).

KEIGHLEY TEXTILE SOCIETY (at Kiosk Café, Keighley), at 7.30.—J. Starkie: Artificial Silk Weaving.

TUESDAY, OCTOBER 21.

ROYAL GEOGRAPHICAL SOCIETY (in New Hall), at 3.—Reception, and Inauguration of Centenary Proceedings.

ROYAL SOCIETY OF MEDICINE, at 5.30.—General Meeting.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Secretary: (a) Report on the Additions to the Society's Menagerie during the months of May, June, July, August, and September 1930; (b) Exhibition of Photographs of Elephants taken by Mr. M. A. Wetherall in the Belgian Congo. Dr. S. M. Manton: Exhibition of Photograph of a Living *Anaspides tasmaniae*.—Miss Rachael M. Renton: On the Budding of a *Scyphistoma*. Dr. W. H. Thorpe: The Biology, Post-embryonic Development, and Economic Importance of *Cryptochaetum iceryae* Will. (Diptera, Agromyzidae) parasitic on *Icerya purchasi* (Coccidae, Monophlebini).—Baron Francis Nopcsa: Notes on Stegocephalia and Amphibia.—P. Gray: The Attachments of the Urodele Rib to the Vertebra and their Homologies with the Capitulum and Tuberculum of the Amniote Rib.—Dr. C. Walter: Report on the Hydracarina (Mr. Omer-Cooper's Investigation of the Abyssinian Freshwaters (Dr. H. Scott's Expedition)).

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—J. D. Johnston: Presidential Address.

ROYAL GEOGRAPHICAL SOCIETY (in New Hall), at 8.30.—Centenary Meeting: Addresses on the History of the Society by Sir Charles Close (President), D. Freshfield, Sir Francis Younghusband, the Marquess of Zetland, and Dr. H. R. Mill.

WEDNESDAY, OCTOBER 22.

ROYAL GEOGRAPHICAL SOCIETY (in New Hall), at 10.30.—Papers on The Habitable Globe by Invited Geographers, British and Foreign.

INSTITUTE OF FUEL (in Incorporated Accountants Hall, Victoria Embankment), at 11 A.M.—Sir David Milne-Watson: Presidential Address.—J. Lubbock: The Industrial Uses of Fuel Oil.—Dr. E. W. Smith: The Use of Coke Breeze for Industrial Purposes.

LIVERPOOL ENGINEERING SOCIETY (at 9 The Temple, Liverpool), at 6.30.—J. L. Adam: Notes on Surveys of Ships.

LEICESTER LITERARY AND PHILOSOPHICAL SOCIETY (Chemistry Section) (at College of Technology, Leicester), at 8.—S. F. Burford: Progress of Chemistry.

TEXTILE INSTITUTE (Midland Section) (at University College, Nottingham), at 8.—A. N. Shimmin: Some Reactions of Foreign Competition on British Trade.

BRITISH PSYCHOLOGICAL SOCIETY (Medical Section) (at Royal Society of Medicine), at 8.30.—Dr. T. R. Hill: Emotion from the Neurological Standpoint.

THURSDAY, OCTOBER 23.

ROYAL GEOGRAPHICAL SOCIETY (in New Hall), at 10.30.—Continuation of papers on The Habitable Globe.—At 3.—Incidents in the History of Exploration: Brief papers by Lord Lugard, Sir Martin Conway, Sir Francis Younghusband, Sir Halford Mackinder, Col. H. Bury, J. M. Wordie, and others.

INSTITUTE OF FUEL (in Incorporated Accountants Hall, Victoria Embankment), at 10.45 A.M.—S. B. Freeman, Dr. W. W. M. Meijer, W. J. Muller, W. L. Roxburgh: Symposium on Fuel Problems in the Mercantile Marine.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—C. C. Paterson: Presidential Inaugural Address.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. J. Kerr: The Whole Child.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 6.30.—F. W. Meredith: Air Transport in Fog.

CHEMICAL SOCIETY, at 8.—A. W. Chapman: Dynamic Isomerism Involving Mobile Hydrocarbon Radicals. Part II. The Intramolecular Character of the Amidine Rearrangement.—A. W. Chapman and C. H. Perrott: Dynamic Isomerism Involving Mobile Hydrocarbon Radicals. Part III. Some Effects of Substitution on the Velocity of Interchange and Position of Equilibrium of Isomeric Triarylbenzenylamidines.—G. G. Davies, Prof. I. M. Heilbron, and W. M. Owens: The Unsaponifiable Matter from the Oils of Elasmobranch Fish. Part VII. The Synthesis of α-glyceryl Ethers and the Constitution of Batyl, Selachyl, and Chimyl Alcohols.—Prof. I. M. Heilbron and D. G. Wilkinson: The Unsaponifiable Matter from the Oils of Elasmobranch Fish. Part VIII. The Structure of the Naphthalene Hydrocarbon derived from Squalene.—Prof. I. M. Heilbron and F. S. Spring: Studies in the Sterol Group. Part X. Hydrocarbons of the Ergosterol Series and the Nuclear Structure of Ergosterol.—Miss N. I. Fisher and Miss F. M. Hamer: A General Method for the Preparation of Thiocyanine Dyes. Some Simple Thiocarbocyanines.

FRIDAY, OCTOBER 24.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at Newcastle-upon-Tyne), at 6.—J. McGovern: Presidential Address.

INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.—J. L. Hodgson and others: Discussion on What are the Desirable Objectives of the Age of Power?

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—A. P. Morris: Bitumen Emulsions, with Particular Reference to their Use on Indian Roads.

LEICESTER TEXTILE SOCIETY (at Victoria Hall, Leicester), at 7.30.—E. Lomas: Pure Silk Manufacture.

INSTITUTION OF CHEMICAL ENGINEERS (Graduates' and Students' Section).—J. E. Duckham: Lubrication as applied to Chemical Engineering.

SOCIETY OF CHEMICAL INDUSTRY (Liverpool Section) (at Liverpool University).—Dr. P. Lewis-Dale: Chemistry in the Service of the Railway.

ASSOCIATION OF ECONOMIC BIOLOGISTS.

PUBLIC LECTURES.

FRIDAY, OCTOBER 17.

LONDON HOSPITAL (in Bearsted Clinical Theatre), at 4.15.—H. S. Souttar: Radium in the Service of Surgery (Schorstein Memorial Lecture).

SATURDAY, OCTOBER 18.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Prof. J. R. Ainsworth Davis: The Uses of a Tail.

MONDAY, OCTOBER 20.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, at 5.30.—Prof. K. Freudenberg: Some Aspects on the Structure of Cellulose and other Polysaccharides; with Remarks on the Constitution of Lignine. (*Oct. 20 and 21.*)—Researches on the Constitution of Insuline. (*Oct. 22.*)

UNIVERSITY COLLEGE, LONDON, at 5.30.—W. N. Weech: More Roman Towns in North Africa.

TUESDAY, OCTOBER 21.

KING'S COLLEGE, LONDON, at 11 A.M.—S. P. Turin: The Economic Geography of U.S.S.R.: Population.

GRESHAM COLLEGE, at 6.—Sir G. Newman: Physic. (Succeeding Lectures on Oct. 22, 23, and 24.)

WEDNESDAY, OCTOBER 22.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Prof. W. S. Lazarus-Barlow: The Prevention of Pre-Cancerous States and the Arrest of Cancer.

BRITISH SCIENCE GUILD (at Liverpool University), at 5.30.—Lt.-Col. Sir David Prain: Science Discipline (Alexander Pedler Lecture).

THURSDAY, OCTOBER 23.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—A. Goodman: Some Medico-Legal Aspects of Contraception.

LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE, at 5.—Prof. L. T. Hogben: Some Biological Aspects of Population.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE (Public Health Division), at 5.—Sir Leonard Hill: Clothing and Climate.

BRITISH MEDICAL ASSOCIATION (Hastings Hall, Tavistock Square), at 5.15.—Dr. F. Bach: Rheumatism: its Significance in Youth and Middle Age (Chadwick Lecture).

BEDFORD COLLEGE FOR WOMEN, at 5.15.—Miss L. Grier: Changes in Occupations and Leisure of Women from 1830 to 1930.

KING'S COLLEGE, LONDON, at 5.15.—Dr. A. D. Lindsay: Hegel and the German Idealists. (Social and Political Ideas of some Representative Thinkers of the Age of Reaction and Reconstruction.)

FRIDAY, OCTOBER 24.

UNIVERSITY COLLEGE, LONDON, at 5.30.—Prof. A. Penck: The Relations of Europe and Central Asia. (Succeeding Lecture on Oct. 27.)

SATURDAY, OCTOBER 25.

UNIVERSITY OF BRISTOL (in Henry Herbert Wills Physical Laboratory), at 11.45 A.M.—Prof. J. Franck: Relations between Spectroscopy and Chemistry (Henry Herbert Wills Memorial Lecture).

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. C. Ainsworth Mitchell: Stories told by Hairs and Fibres.

SATURDAY, OCTOBER 25, 1930.

Professional Registration.

A SIGNIFICANT feature of professional life in post-War Europe to which the Committee on Intellectual Co-operation of the League of Nations has several times directed attention, is the tendency of professional workers to organise themselves in defence associations and frequently to attempt to establish a register of those qualified to practise, accompanied by legal restriction of professional practice to such persons. The case of the accountant, against which a Departmental Committee has recently reported, is the latest in sequence of a series of unsuccessful attempts to establish such registers in Britain. Restrictive registration was granted to the profession of dentistry in 1921. An architects registration bill was unsuccessfully introduced into the House of Lords in November 1928, and a similar attempt to obtain registration of opticians proved abortive in 1927, strong opposition being displayed in the House of Commons by the medical profession. In the profession of science, like tendencies are to be discovered, notably in the profession of chemistry, and it is probably largely the anomalous position in which the chemist finds himself in Great Britain, where the title of chemist is already restricted by law to the pharmacist, that has delayed the presentation of a bill before Parliament. The Pharmacy Bill which was presented to Parliament by certain private members in 1923, although it proposed to restrict the title of chemist to persons registered by the Institute of Chemistry, was drafted without consulting the professional organisations of chemists, such as the Institute of Chemistry and the British Association of Chemists, and did not represent a professional movement for registration.

While such attempts have in some cases proved premature from various causes, they indicate a tendency towards a definite change in the social structure of the country. To the more artificial system of political parties the growth of professional organisations, like that of the trades unions, opposes an occupational organisation similar to that of the medieval guild system. It is not, of course, contended that until recently professional organisation has not existed or that professional registration has not been tried. What is new is the expansion in the numbers of scientific workers and the growth of the professional spirit. Such workers have almost inevitably contrasted their own position with that of members of the medical profession, and the development of the medical profession since the passing of the Medical Act of 1858 has proved

a powerful stimulus to other and younger professions to seek similar lines of development as they become sufficiently numerous or important. In the field of science, the activities of the Association of Scientific Workers and of the British Association of Chemists illustrate this tendency. The former has debated the formation of a General Scientific Council and the institution of a Science Act, while the latter has recorded among its definite objects the legal re-definition of the term chemist and the formation of a legal register of all who are qualified to practise chemistry.

The newer branches of the profession of science, however, in contrast to the older professions of medicine and law, suffer the handicap that their members are rarely in direct relation with the public but are mostly themselves employed persons, and this factor constitutes a main difficulty in a movement towards registration.

There are two main obstacles to the activities of both these organisations. The Association of Scientific Workers is handicapped by sectionalism among scientific workers and the absence of real co-operation between different branches of science. In particular, the Association has not yet received any full measure of support from the most numerous class of scientific worker at the present time—the chemist—probably in consequence of the relatively highly organised position of the profession of chemistry. Indeed, while there is a profession of chemistry, it is doubtful whether we can speak with as much truth of a profession of science. The British Association of Chemists, while not altogether free from the handicap of lack of co-operation between different branches such as the consultant or analyst and the industrial chemist, finds a main obstacle to its progress in the question of title and the existence of the Pharmacy Acts. In a memorandum upon the questions submitted by the Departmental Committee on the Poisons and Pharmacy Acts, the Council of the Pharmaceutical Society recently recognised that other persons than those registered under the Pharmacy Acts practise chemistry in its different branches without statutory recognition. While persisting in the view that the title chemist could not be relinquished by pharmacists, the Council suggested that the creation of a register of chemists in which persons registered under the Pharmacy Acts took their place as pharmaceutical chemists would overcome the difficulty. The suggestions as to the means of producing such a register are left to the initiative of organisations representing chemists. Such an inclusive register might well remove the immediate difficulty, but the drawbacks to a register including the members of two entirely distinct professions are obvious. Alternative titles have been suggested, and the term "chemical practitioner" adopted by the British Association of Chemists, although cumbersome, has found some support. When, however, a sufficient volume of organised support for the registration proposal is forthcoming from the profession of chemistry, the question of title is unlikely to prove a permanent obstacle.

Even the failure of movements towards professional registration may indicate or emphasise the conditions essential for success. Primarily the desire for professional registration arises from a belief among members of a profession that such a step would result in an improved status and economic position for the members of that profession. While such aims are justifiable, they would not be accepted as a main reason for closing the profession. It must be shown that the enhanced status by, for example, increasing the efficiency of the services rendered would be an industrial or public advantage.

Although formed largely to defend the economic interests of their members and to fill a definite gap among the existing organisations of science, the Association of Scientific Workers and the British Association of Chemists have never pursued a narrow policy, but have endeavoured to awaken a wider sense of public responsibility among scientific workers and secure their fuller participation in public affairs. Although the latter body is still registered under the Trade Union Acts, neither organisation has ever shown any tendency to associate itself with the militant side of trades unionism. Trades unions have their own value in the present structure of industry, and scientific professional organisations deeply imbued with a spirit of service might well exercise an influence out of all proportion to their numerical strength, given the right opportunities of contact.

As it is, in such newspaper references as are made to the activities of either the Association of Scientific Workers or the British Association of Chemists, there is a tendency to stress unduly their material or economic interests and to ignore their wider aims. The two are, however, inseparable. No branch of science can render its full service to the State whilst its members are relatively handicapped in status or pay. First-class work, or the necessary proportion of first-class men, cannot be expected as the result of second- or third-class treatment. On the other hand, any great improvement in such respects can only come as scientific workers succeed in bringing home to the general

public their wider aim and educating the community in the value and place of pure science.

Under present conditions both these aims are of urgent importance. We have alluded recently to the dearth of first-class recruits for pure research. It is equally important to the community that science should assume a fuller share of responsibility for leadership and take a much wider part in public affairs. The relation between the scientific worker and the control and ordering of the life of the community under the impact of applied science presents a difficult problem for democracy. Some of the most complex situations confronting statesmen to-day can be traced directly to the indifference of those responsible for the discoveries of science to the consequences attending their utilisation. Scientific workers have been so absorbed in the progress of their researches that they have frequently neglected to take their share in assisting the control of forces which have been released by their work. This is the point on which Prof. Zimmern and other workers in the field of intellectual co-operation insist, and the wider recognition to-day of the importance of a right relationship between science or learning and leadership is largely due to their efforts.

Those scientific workers who have most clearly envisaged the contribution which science can make to the security and welfare of the State, and who are eager to see scientific workers taking full responsibility in the community, are among the most convinced supporters of the movement towards professional registration. The professional organisation which must precede registration offers some prospect of counteracting the political impotency of science in Great Britain. The publicity which such a movement requires and obtains serves to give a much-needed platform from which the services the chemist or other scientific worker renders to the community can be broadcast. The influence of science on public affairs as well as upon industry is now so profound and so rapidly increasing that in most branches of science an effective case could probably be presented for registration as in the public interest. The fact that the benefits of registration accrue slowly—a space of anything up to fifty years is required to eliminate from the register the lesser qualified persons who must be admitted in the first instance—only adds urgency. In a society the structure of which is increasingly dependent on the results of modern scientific discoveries, and in which ignorance or disregard of scientific facts can have far more serious consequences, measures to maintain or enhance high standards of qualification and integrity in those who practise in any branch of science are essential and demand public support.

For another reason the growth of professional organisation, if not of professional registration, among scientific workers may prove a public advantage. The solution of many important problems to-day is determined by factors which can be resolved by impartial and scientific inquiry. No forum exists from which those findings can be effectively made known without distortion by vested or political interests and from which, if necessary, unprejudiced public opinion can be organised to secure appropriate action. It is at least possible that the growth of professional registration will assist in the removal of one of the fundamental defects of modern democracy—the difficulty of securing for the community the advantages which would result from the enforcement of the recommendations of an impartial tribunal when its findings are not entirely in accord with the declared policy of any powerful party, or are, as is usually the case, regarded with disfavour by those whose interests are most immediately concerned.

The Problem of Epigenesis.

(1) *Grundriss der Entwicklungsmechanik.* Von Prof. Dr. Bernhard Dürken. Pp. vii + 208. (Berlin: Gebrüder Borntraeger, 1929.) 12·50 gold marks.

(2) *Die Determination der Primitiventwicklung: eine zusammenfassende Darstellung der Ergebnisse über das Determinationsgeschehen in den ersten Entwicklungsstadien der Tiere.* Von Prof. Dr. Waldemar Schleip. Pp. xii + 914. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1929.) 85 gold marks.

(3) *Experimentelle Zoologie: eine Zusammenfassung der durch Versuche ermittelten Gesetzmässigkeiten tierischer Formen und Verrichtungen.* Von Prof. Dr. Hans Przibram. Band 6: *Zoonomie; eine Zusammenfassung der durch Versuche ermittelten Gesetzmässigkeiten tierischer Formbildung (Experimentelle, theoretische und literarische Übersicht bis einschliesslich 1928).* Von Prof. Dr. Hans Przibram. Pp. viii + 431 + 16 Tafeln. (Leipzig und Wien: Franz Deuticke, 1929.) 40 gold marks.

THE question of epigenesis may be justly said to constitute one of the two root problems of zoology. For if we think it out there are two main things to be discovered about an animal, namely: (1) How does it fulfil its functions?—in a word,

considered as a machine, how does it work? and (2) How does it come into being?—that is, how did it develop and grow? A subsidiary question to the last is: If there be such a thing as evolution, how and why did the powers of growth change from generation to generation? For, as the late Dr. Bateson reminded us so long ago as 1894, the conception of evolution as the remoulding of the adult structures of an animal as we could alter the features of a wax doll by melting the wax and remodelling it, is an entire illusion, since the members of the parent species and of that to which it gives rise both begin as tiny formless germs and what is changed is *the powers of growth*. Now when we begin to analyse growth, we can either directly observe its successive phases—and this is the scope of descriptive embryology; or by operating on the germ by chemical and physical agencies we can seek to discover the part which each visible element plays in the upbuilding of the adult individual—and this is the object of experimental embryology.

How this science has grown since its first beginnings with His in 1874 ("Unser Körperform und die physiologische Problem ihrer Entstehung") is witnessed by the three splendid works which are the subject of this review. Each of the three is worthy of unstinted praise: though we may differ from the authors in some of the conclusions reached by them, yet in each case the collection and setting forth of the matter is worthy of our sincere admiration. We hope that too long a time may not elapse before all are translated into English.

As an introduction to the subject Dürken's manual is to be preferred, because it is concise, well illustrated, and includes only typical cases which serve to exemplify the main principles of the subject, so that a beginner can get a good grasp of these principles without being overwhelmed by too much detail. Schleip's large and well-illustrated volume attempts to give a more or less complete account of the present state of our knowledge of the subject, and it will for a long time constitute a classic work of reference. Przibram's work—thorough and excellent as all his work is—is even more ambitious in its scope than that of Schleip, for it includes not only the facts of experimental embryology in the narrower sense, but also a considerable amount of the results of Mendelian experiments. It is, however, extremely condensed and, not being adequately illustrated, somewhat difficult to follow: it seems to us that its chief value will reside in its being a manual in which references to all the important papers on the subject can be easily looked up.

It must be obvious to the reader that, within the limits of the longest review for which space can be found in Nature, it would be impossible to refer to a tithe of the new matter contained in these volumes, and so we must limit ourselves to a discussion of the main problems involved and to the attitude of the three authors towards them. In fairness, however, it should be added that this new matter is almost entirely confined to an elaboration of subjects dealt with by the older authors such as Roux, Hertwig, Driesch, Herbst, Boveri, Conklin, and Wilson, and does not consist to any considerable extent of discoveries in newer fields. The number of animals the eggs of which can conveniently be handled and which are tolerant of experiments is limited, and the same familiar figures crop up in successive text-books of experimental embryology. After all, as Driesch has wisely remarked, the biological experimenter cannot produce life at will—he must wait until he finds it, and he is therefore in the same position as a physicist would be if he could only study fire when he found it in the crater of a volcano.

When we approach the analysis of the development of the egg, the first question we encounter is whether the organs of the adult exist in the egg preformed in miniature and development consists essentially in an unfolding and growing bigger of these rudiments, or whether the egg is at first undifferentiated material which from unknown causes afterwards becomes more and more complicated and development is consequently an 'epigenesis'. This problem is *the* problem of experimental embryology; in varied forms it reappears in every experiment on development which has been made.

The answer to this question given by the earlier experiments of Driesch was that some eggs, such as those of starfish and sea-urchins, consist of undifferentiated material; but others, like those of Ctenophores, show a specialisation into parts destined to form particular organs of the adult. The experiments of Wilson, Conklin, and Crampton proved that the eggs of Annelida and Mollusca belong also to this latter category. To eggs of the first kind Driesch gave the name of 'equipotential systems', since when the egg had divided into eight cells any one of these was capable of forming a tiny larva perfect in all details, and, moreover, when the egg had developed into a hollow sphere or blastula, any considerable piece of this blastula would round itself off and form a perfect blastula of reduced size, which would give rise to a correspondingly reduced larva. On these results, which were a complete surprise to him, Driesch founded his

theory of vitalism, arguing that if the organism were to be regarded as a physico-chemical machine, such things could not happen, for no conceivable machine could be divided into parts, each of which would function as a similar machine of reduced size. He inferred that there must be in every egg a non-material force or 'entelechy' which was capable of controlling the physical and chemical changes taking place in the germ, so as to direct them towards a definite end. This power of direction was named by Driesch 'regulation'. This revolutionary idea of Driesch, transcending the bounds of materialistic explanation, evoked the fiercest opposition amongst those biologists by whom life was regarded as nothing more than complicated chemistry. Yet the arguments of Driesch have never been successfully met. The utmost that can be urged against them is the assertion that, although we cannot explain life by physics and chemistry now, some day in the distant future, when we have made further discoveries, we may possibly be able to do so.

Of the authors reviewed in this article, Dürken is inclined to favour Driesch whilst Schleip and Przibram oppose him, but the alternative explanations of the two latter authors when examined in detail resolve themselves into saying the same things that Driesch said, in different phrases. All three authors agree in showing that between equipotential and specialised eggs every conceivable grade of intermediate exists, and that even the eggs of *Echinus* itself are not quite so equipotential as Driesch imagined. Schleip quotes the work of Hörstatius as proving that when the upper half of a blastula is cut off, though it will round itself off so as to form a reduced blastula, yet this will never form endoderm or proceed any further in development. The vegetative half, however, when severed will produce a completely viable gastrula. By a triumph of manipulative skill, Hörstatius succeeded in separating the vegetative pole of a blastula and grafting it in various positions on another blastula in which an appropriate defect had been produced. He thus proved that in all cases development begins in the graft, and that this graft can change cells that would otherwise produce ectoderm into endoderm, in other words, act as an 'organiser' of development.

Driesch attributed specialisation in eggs to a 'premature stiffening of the cytoplasm' which prevented the 'entelechy' from moulding the fragment of the egg into a reduced whole. Przibram in other language comes to exactly the same conclusion. He says that the formation of definite organs is in all cases due to a *solidifying* of a portion of the cytoplasm, forming what he calls an 'apoplasm' which, if we understand him right, he does not regard as fully alive. In proportion as 'apoplasms' are deposited the potentialities of the germ are successively limited, and the reason why the higher animals approximate in their working to mechanisms is the large number of 'apoplasms' included in their make-up. Only fluid cytoplasm is completely living and possesses all the potentialities of the race, and Przibram is driven to conclude that these potentialities, so far as embodied at all, must be contained in the molecules of the cytoplasm, and that, therefore, these molecules constitute the real entelechy. Schleip similarly concludes that there must be an ultra-microscopic structure in the cytoplasm which, like a crystal, tends to assume a definite form and to complete itself when a fragment is severed.

In making these admissions, however, it seems to us that both Schleip and Przibram deliver themselves into the hands of Driesch. For in the crystallisation of an inorganic substance from a solution, the crystal assumes a definite form because its molecules have definite corresponding shapes, as Sir William Bragg has taught us. But what kind of structure, whether molecular or super-molecular, are we to envisage in cytoplasm? When the limb of a young newt is cut off and the stump proceeds to regenerate a new limb, are the molecules in the stump in the form of infinitesimal fingers and toes? Moreover, when the stump is cut at different levels and only the missing piece is regenerated, are we to assume that at each level in the limb before amputation the molecules are miniatures of the part distal to them? If we are able to swallow these fantastic assumptions, what are we to say of the experiment recorded by Dürken in which the tail bud of one newt embryo was grafted into the body of another near its forelimb and developed into a new limb? Presumably the cytoplasm of the tail bud was 'organised' so as to produce the tissues of an adult tail. How then was this organisation so completely changed as to produce a limb instead? No wonder that Dürken says that in cases like this, physical and chemical explanations leave us completely in the lurch, and we must have recourse to the conception of the 'biological field', an influence not in the living matter itself, but in the space, presumably the ether, around it.

Schleip seeks to disprove Driesch's theory by pointing out that the supposititious entelechy sometimes does foolish things, as in the case of the eggs

of Nematoda subjected to centrifugal force each of which produces two partial embryos instead of one whole one. But in this objection lurks the childish conception that the entelechy, if it exists, must be the embodiment of Divine Wisdom. The entelechy is not all-seeing—it is a rudimentary 'striving' which reacts to its immediate environment, in this case the 'apoplasm' or ball of dead matter ejected from the egg by centrifugal force.

The term 'organiser' we owe, of course, to Spemann, who wisely abstains from giving any chemical explanation of it. In the course of his marvellous experiments on the newt, Spemann showed that a piece of the dorsal lip of the blastopore of one newt gastrula grafted on the flank of another would change the fate of all the cells in its neighbourhood and force them to develop into a supplementary nerve-cord and underlying notochord. The reviewer might humbly plead that exactly the same conception was reached by him and published in a paper which appeared in 1918 entitled "The artificial production of Echinoderm larvæ with two water-vascular systems and also of larvæ devoid of a water-vascular system" (*Proc. Roy. Soc.*, B, vol. 90). In this paper he showed that when under the stimulus of hypertonic sea-water a second hydrocœle bud was produced in the pluteus, it completely altered the fate of all the tissues near it. It unfortunately did not occur to him to invent the term 'organiser'.

Of what nature is the influence emitted from the 'organiser'? Here again all physical and chemical analogies fail to help us. If the influence were merely a physical or chemical force it would *combine* with the growth-forces of the organised tissue, and what we should observe would be the *resultant* of the two forces. The complete domination of one part by another is not a physical but a vital phenomenon and an instance of Driesch's 'regulation'.

It would be a fair conclusion to draw from all that has been discovered in the field of embryology to say that in broad outline there are three stages in development, namely: (1) Division of the egg into cells—that is, segmentation; (2) differentiation of these cells so as to form the three primary layers—ectoderm, endoderm, and mesoderm; (3) the action of portions of one layer on the neighbouring parts of other layers so as to form definite organs—that is, the action of organisers.

The ultimate question, however, whence the original organisation of the cytoplasm of the egg is derived, must now be faced. The only answer possible is the nucleus. It is true that, as we have seen, many eggs when ready for fertilisation have an already differentiated cytoplasm. But the cytoplasm of these eggs *when young* is undifferentiated, and during ripening their nuclei are engaged in emissions into the cytoplasm. In particular the nucleolus has been repeatedly observed to become broken into fragments which pass through the nuclear membrane and become dissolved in the cytoplasm. If we take such a specialised egg as that of the Nematode *Ascaris*, Boveri has shown that if it is subjected to centrifugal force *when young*, large portions of the cytoplasm can be shorn away and yet the reduced egg will give rise to a typical embryo. To this conclusion Schleip and Przibram also consent. But it seems to us that a further conclusion follows which they have not clearly envisaged. When differentiation of the cells of the blastula takes place, this must be due to further emissions from the nuclei. But the nuclei in these early stages of development are all alike, and by means of pressure experiments, these nuclei, as Hertwig has put it, may be juggled about like a heap of marbles without altering the result. Moreover, so far as can be judged by the most minute cytological examination, they remain unchanged in their essential make-up throughout the whole of development. So we reach the conception of an *intermittent action of the nuclei on the cytoplasm* giving rise to successive differentiations, that is, stages of development; and as it is by means of these stages that development is directed towards a definite end, if there be an entelechy, we may conclude that the mode of its action is by nuclear emissions. These emissions are the physical correlates of what Uexküll in his "Theoretische Biologie" (1927) calls the 'Impulse' to development and the distinguishing of which, he avers, constitutes the utmost limit to which biological analysis can go.

Comparative embryology, however, can go further, and Schleip rightly insists that experimental embryology ought to be comparative. These embryonic stages are soon discovered to be merely smudged and simplified forms of larval stages which in allied forms lead a free life in the open, seeking their own food and combating their own enemies. These larval forms in turn are seen to be nothing but modified and simplified editions of adult forms in the past history of the race. Therefore, in the last resort, development is found to be due to the successive coming to the surface of a series of racial memories, and the entelechy might be defined as a 'bundle' of such memories.

The so-called Mendelian 'genes', however, constitute a problem for the embryologist; for the

conception of the hereditary make-up which they induce in the minds of geneticists is totally at variance with that which the embryologist draws from the study of development. Schleip and Przibram struggle valiantly to reconcile the two conceptions and fail. Dürken alone boldly questions the validity of the whole conception of the genes and points out how much it is purely arbitrary and theoretical. If the results of a crossing experiment agree with expectation based on the ordinary Mendelian rules, then it proves the reality of genes; if the results do not agree, the geneticist denies that it disproves them, because he immediately postulates the action of an undiscovered 'gene' which complicates the result. The real answer to the conundrum was given by Johannsen, when, in his latest publication, deploring the damage and confusion of thought caused by the invention of the word 'gene', he states that it represents a mere superficial disturbance of the chromosomes and gives no insight into the real nature of heredity. Even Przibram points out that X-rays will produce "unzählige" mutations, and that there is no correlation between the rays and the nature of the mutation. With these remarks we thoroughly agree.

E. W. MACBRIDE.

Fourier's Series.

Introduction to the Theory of Fourier's Series and Integrals. By Prof. H. S. Carslaw. Third edition, revised and enlarged. Pp. xiii + 368. (London: Macmillan and Co., Ltd., 1930.) 20s. net.

PROF. CARSLAW'S excellent book is so well known that it needs little general introduction. The first edition, published in 1906, was a work on "Fourier's Series and Integrals and the Mathematical Theory of the Conduction of Heat". The second edition followed in 1921, in two volumes. The great advances in the theory of Fourier's series had caused the earlier chapters to develop into a self-contained book on analysis, including much matter on sequences and integration in addition to the theory of Fourier's series. It is of this work that the present book is the new edition.

Though there has been no radical change in character, much new matter has been introduced. In the old edition the discussion of the convergence of Fourier's series was limited to functions satisfying Dirichlet's conditions. This was unsatisfactory, because the sum of two such functions need not satisfy the conditions. The notion of functions of bounded variation has now been introduced, and the discussion has been enlarged so as to include them. Perhaps at this point it would have been well to make clear that (as is proved in a later chapter on the Riemann-Lebesgue lemma) the condition of bounded variation need only be satisfied in an arbitrarily small interval surrounding the point at which the convergence is considered. The difficulty could have been avoided by proving the Riemann-Lebesgue lemma at an earlier stage. In passing, it is perhaps worth while to suggest that the familiar and cumbrous condition "if x is an interior point of an interval (a, b) in which $f(x)$ has bounded variation" might well be shortened to "if the limits $f(x \pm 0)$ exist absolutely". The relation between the condition just mentioned and the condition "if the limits $f(x \pm 0)$ exist" is exactly parallel to that between absolutely and non-absolutely convergent series.

An account of Parseval's theorem (for a bounded R-integrable function) is another noteworthy improvement. In the excellent chapter on Gibbs's phenomenon, Prof. Carslaw records his interesting discovery that the phenomenon was pointed out by one Wilbraham, of Trinity College, Cambridge, more than fifty years before Gibbs's famous letter to NATURE.

There is again an appendix on practical harmonic analysis and periodogram analysis. The first part of this is the 'practical' complement to the real variable theory of the preceding chapters, but the later work is still without a counterpart in real variable analysis. The analogy between the practical methods of periodogram analysis and certain results concerning almost periodic functions suggests a possible source for the appropriate theory.

In place of the bibliography in the old edition, there is an appendix on the theory of sets of points, leading up to the Lebesgue integral and its application to Fourier's series. Like all the rest of the book, this is clearly and attractively written. One can only wish that there had been more of it and that it had been incorporated into the book at an earlier stage. If the theorems on Fourier's series which involve the notion of measure are harder than those which do not, they are far more interesting and illuminating. Moreover, there is need for an English book on the subject of moderate size. In taking leave of the third edition, we may express the hope that in the fourth Prof. Carslaw will enlarge or again subdivide his book to supply this need.

Scientific Nominalism.

Les concepts scientifiques. Par Hélène Metzger. Ouvrage couronné par l'Académie des Sciences morales et politiques. (Bibliothèque de Philosophie contemporaine.) Pp. x+196. (Paris: Félix Alcan.) 12 fr.

THE twentieth century, and especially the last decade, has seen a remarkable development of consideration by working scientists of the philosophic implications of their labours. Biologists, as well as workers in the physical sciences, are studying the theory of knowledge in the light of their own work.

In the volume before us, Madame Metzger endeavours to generalise the categories within which scientific concepts may be grouped. She starts from the thesis that classification is a primal need of the human mind. We need to sort out the infinite complexity of experience, to make some choice of the matter of our own thought. Only by what is in ultimate analysis a process of classification can we embrace many phenomena in a single series of considerations.

Classification, Madame Metzger points out, is necessarily based on analogy, which may be to a greater or a lesser extent the construction of the mind itself. In considering a group comprising a number of phenomena or of series of phenomena, the mind so frames the boundaries, both of the group itself and of each series within the group, that they may conform to the analogical framework within which the mind chooses to work.

Having established the thesis that classification, based on analogy, provides the foundation of all mental activity, including that of the scientist, Madame Metzger proceeds to the analysis of the various patterns of those groupings of experience that underlie the formulation of various hypotheses that have held the field in science, and especially in chemical science. In each theory she traces the use of analogy as the basis of the concept of scientific law. Almost as pervasive as the concept of analogy is, she shows, that of evolution or development, which she distinguishes as "divergent, parallel, or convergent", each in turn based on analogy, that is, on a grouping of phenomena in such a fashion that it may be possible to ascribe to each group certain common properties or common relationships, while the groups themselves, considered as entities, may be similarly connected by common properties or relationships. "Perhaps", says Madame Metzger, "the complete image of Nature cannot be embraced in the monument erected by human intelligence . . . but the partial success attained assures us that evolutionist frameworks are, at least to some extent, in harmony with reality."

The final part of the work considers to what extent 'scientific nominalism' does in fact extend our interpretation of scientific concepts, and ends on a warning that classification tends always to be based on a process of abstraction which gives only a partial reflection of Nature.

DOROTHEA WALEY SINGER.

Our Bookshelf.

The Science of Folk-Lore. By Dr. A. H Krappe. Pp. xxii + 344. (London: Methuen and Co., Ltd., 1930.) 10*s.* 6*d.* net.

DR. KRAPPE was inspired to write this survey of the field of folk-lore by his visit to the congress held in London in 1928 to celebrate the jubilee of the Folk-Lore Society. The necessity for such a handbook was presented to him through his opposition to the methods and outlook of the so-called 'anthropological school'. Hence the existence of a handbook, published by the Society and prepared under the editorship of the late Miss C. S. Burne, is not mentioned. Throughout Dr. Krappe is very critical of Andrew Lang and the colleagues who with him were the foremost exponents of the anthropological method in Great Britain, nor will he admit the historical point of view of the late Sir Laurence Gomme. Nevertheless, he recognises the results achieved by the anthropological method in the hands of such a master as Frazer, whom indeed he regards as transcending all schools. He himself belongs to the school which subjects the material of folk-lore to the strict canons of literary and historical criticism.

Dr. Krappe, of course, has no difficulty in showing that the results attained by the uncritical application of the anthropological method are often unwarranted and sometimes absurd. That, indeed, might apply to any method injudiciously used. On the other hand, while the method of which he is the exponent may prune away some exuberances in the handling of fairy tale, folk-tale, and myth, as has already been done by certain English writers, yet even in Dr. Krappe's treatment of such subjects as magic, ritual, and superstition, the interpretation of the ultimate residuum after the application of the literary method must rest with the comparative method of the anthropologist whether the matter *sub judice* be an independent invention or the result of diffusion from a single origin.

Romance of the Planets. By Mary Proctor. Pp xii + 272 + 8 plates. (New York and London Harper and Bros., 1929.) 7*s.* 6*d.* net.

MISS PROCTOR must certainly be counted unfortunate in having brought out this little book just before the discovery of the extra-Neptunian planet, Pluto She has narrowly missed being the author of the one up-to-date book on the planets, and the romance

of the discovery is by no means the least interesting aspect of it. However, she is in time for the forthcoming opposition of Eros, and her diagram of the path of the asteroid on that occasion should be of particular interest just now. The book is the fourth of a series dealing with the various bodies in the solar system. "These books have no scientific pretensions," says the preface, "nor do they deal with heavy celestial mechanics or troublesome mathematics; rather do they incline to an account of the latest theories and advances in astronomical research given in an entertaining, conversational manner." Books of this kind will always have their use, and "The Romance of the Planets" may be recommended as a very readable and accurate account of its subject, requiring the minimum of intellectual effort on the part of the reader. The question of the habitability of the planets is well to the fore, and is treated historically with numerous quotations. Quotations, in fact, are a prominent feature of the book, and are usually apt, though it is with something of a shock that we find Tennyson's almost hackneyed lines:

"the great world's altar-stairs
That slope through darkness up to God",

attributed to F. A. Pouchet! The illustrations are well chosen and moderately well reproduced.

Alternating Current Bridge Methods: for the Measurement of Inductance, Capacitance and Effective Resistance at Low and Telephonic Frequencies; a Theoretical and Practical Handbook for the Use of Advanced Students. By Dr. B. Hague. (The Specialists' Series.) Second edition, revised and enlarged. Pp. xvi + 391. (London: Sir Isaac Pitman and Sons, Ltd., 1930.) 15*s.* net.

THIS book is a theoretical and practical handbook for the use of advanced students. The best methods at present in use for measuring inductance, capacitance, and effective resistance both at low and at telephonic frequencies are given. The considerable amount of new matter in this edition has in our opinion increased its usefulness.

During the past six years, several notable uses of the alternating current bridge method to practical measurements have been made and these are duly described. An immense amount of research work has recently been done on the measurement of dielectric losses in cables and insulators at very high voltages, and bridge methods have been found as a rule better than wattmeter methods.

The principle of the Kelvin double bridge has been usefully extended to making alternating current measurements. The theory underlying the use of bridge networks is given, and the author's treatment will be easily understood by students. We think the book would be still more useful if the author had included methods of making measurements at radio frequency.

Hints, however, are occasionally given which will be a help to those working at very high frequencies. In particular, the sections dealing with bridges using condensers and the various methods which have to be adopted for shielding them will be found useful.

Deposition of the Sedimentary Rocks. By Prof. J. E. Marr. Pp. vii + 245. (Cambridge: At the University Press, 1929.) 7*s.* 6*d.* net.

PROF. MARR's little volume gives a general account of the conditions which have controlled the distribution of the sedimentary rocks in time and space. It is not concerned except incidentally with the actual characters of the various types of sediments. These are divided according to their mode of origin—primarily into land and sea deposits. The latter are further divided according to the particular belt of sedimentation in which they are believed to have been laid down. These belts are—(i) the 'belt of variables', in which occur those sediments originally deposited nearest the shore line; (ii) the intermediate or 'mud belt'; and (iii) the 'organic belt'.

The introductory chapters discuss chronology and the use of fossils in correlation. The final two chapters consider the relationship between climatic belts and belts of sedimentation, and between the principle of uniformitarianism and organic evolution.

The author's treatment of his subject is throughout philosophical, with a refreshing absence of dogmatism. Detail is only introduced where necessary to illustrate points under discussion. The book forms an excellent introduction to the study of stratigraphy, and may also be recommended to those whose interest in geology is cultural rather than professional.

Morphologic Variation and the Rate of Growth of Bacteria. By Prof. Arthur T. Henrici. (Microbiology Monographs: General, Agricultural, Industrial, Vol. 1.) Pp. xiii + 194. (London: Baillière, Tindall and Cox, 1928.) 13*s.* 6*d.* net.

THIS book comprises a series of personal researches of a statistical character undertaken with the view of attempting to bring order out of the chaos which has so far filled the field concerned with the form and structure of bacteria.

The object of the book is to show that, contrary to orthodox teaching, the cells of bacteria are constantly changing in size, form, and structure in obedience to the operation of relatively simple laws. The author's investigations tend to show that the growth of bacteria in artificial culture is governed by the same laws that affect the development of multicellular organisms; the cells in turn exhibiting an embryonic form during a period of rapid growth, a mature or differentiated form during a period of slow growth or rest, and a senescent form during the period of death.

Altogether a most interesting and stimulating monograph. R. ST. J.-B.

Solvents. By Dr. Thos. H. Durrans. (Monographs on Applied Chemistry, Vol. 4.) Pp. xv + 144. (London: Chapman and Hall, Ltd., 1930.) 10*s.* 6*d.* net.

THIS is a book which deals mainly with the newer solvents for nitrocellulose. Its interest is for the technician engaged in the manufacture of nitrocellulose lacquers and enamels rather than for the general scientific reader.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Fechner-Weber Law in Wool Sorting.

IN the course of research work regarding the determination of the fundamental basis upon which wool 'quality' is assessed, an interesting illustration of Fechner's law has been brought to light.

An examination of a range of worsted tops comprising all qualities usually accepted by the trade from 48's to 80's has yielded interesting results. The tops were selected and vouched for by several authorities in the trade as being typical of their particular quality, and investigation revealed the interesting fact that the mean finenesses of the fibres comprising the samples of successive qualities of wool form a geometric progression. This result is in direct agreement with the Fechner-Weber law which states that "in order that the intensity of a sensation may increase in arithmetic progression the stimulus must increase in geometric progression, or in Fechner's notation $I = c \log S$".

An examination of French, German, and Italian standards has revealed that the same law is followed with, of course, a different number of grades in each country. It is not surprising to find that this should be the case, since the wool sorter's estimate of quality is made through the visual and tactile senses. The fact that the results of wool sorting follow Fechner's law affords a convenient basis for international agreement for an agreed scale of fibre fineness. So far as we are aware, the confirmation of this psycho-physical law, in its application to the wool industries, has not previously been noted.

(Director of Research).

Wool Industries Research Association,
Torridon, Leeds, Oct. 6.

Natural Transport of Stones and Marine Animals.

AN article on the "Transport of Stones by Attached Seaweed" in NATURE of Feb. 8 suggests some interesting lines of thought. During the last two years, I have explored some 600 miles of coast in Western Australia, but have seen nothing comparable to the cases cited below or in the paper quoted, the only feature of interest in this connexion being the *Cymodocea* drift; the long ribbon-like leaves are rolled together by the waves and masses of several tons commonly present a wall two feet high and a chain long to the waves, and so give the beach a temporary degree of permanence, with shallow temporary pools on the landward side.

The case is very different in New Zealand. The coasts of Canterbury include cliffs, reefs, shingle, and sand, and the algal vegetation is luxuriant, including numerous float-bearing fucoids, notably *Cystophora retroflexa*, and also the immense kelps *Durvillæa antarctica* and *Macrocystis pyrifera*. One would expect that under such conditions supporting evidence could be found for Mr. Symington Grieve's views, as quoted in the above article, but although I have several curious observations to offer, I have never seen anything to suggest that stones attached to the holdfasts of algæ contribute materially to the breaking down of cliff faces or to the building up of stone beaches.

The article referred to mentions an account by my former teacher Dr. Charles (not James as given) Chilton, on the transport of stones by ascidians. Sponges are much more frequently concerned; at Timaru, for example, drift sponges may be seen in great numbers on a shingle beach, attached to stones or to the sessile queenshells *Chlamys*. No doubt the increasing size of the sponge leads to the dislodgment of the object to which it is attached, as also happens with fucoids attached to stones or to crumbling limestone or papa rock, or *Macrocystis* on the pinna shell *Atrina zelandica*. But the sponges did not accomplish much in the building up of the Timaru stony beach, which was small until a large mole was built out into the sea a few years ago; the mole not only stops the shingle as it drifts northwards from the mouths of the Pareora and Waitaki Rivers, but also it holds the beach permanently there in a way that *Cymodocea* or sponges could never do. As for the battering of cliffs by suspended stones, the latter are by no means hurled at the cliff, but trail sluggishly along the bottom with the upper fronds of the weed swaying backwards and forwards nearer the surface, and the usual fate of the stones seems to be to get wedged in between other larger stones and held firmly. There is a narrow range in the size of stones transported by any such means, and a small stone and a weed would seem a poor combination in comparison with a good Pacific breaker.

I am, however, the more ready to think that the differences between Mr. Symington Grieve's views and my own impressions are due to genuine local differences, because I can mention a number of curious phenomena which, though possibly paralleled in the North Atlantic, are not mentioned in any accounts which have come under my notice. First, there are rocks in New Zealand which, so far as mechanical forces are concerned, must be more kelp-worn than water-worn. *Durvillæa* invariably grows between tide marks in channels or exposed points where there is a maximum disturbance of the water; at a rough estimate, the discoid holdfasts, which commonly overlap or fuse, are 10 in. across, the stipe is cylindrical and 1½ in. in diameter, the fronds are ½ in. thick, and the whole plant 10 ft. in length. The fronds, which are torn into ribbons by the continued impact on the rocks, are full of air-spaces, and very buoyant, but nevertheless extremely tough. As a wave recedes these fronds trail outwards after it, slithering over one another and over the rock in a dense mass, and the next wave hurls them back by the ton with terrific force against the rock. In some places more kelp strikes the rock than water, and the wearing effect must be much greater. But by a strange oversight, experimental work in New Zealand on the wearing effect of shingle grinding together has not yet been extended in the present direction. Similarly, rocks half buried in sand are devoid of life within a foot or so of the sand, and are no doubt worn down by the suspended sand.

Macrocystis grows below low water mark, at a sufficient depth for its fronds, though many yards in length, to be safe from laceration on the rocks; it thus forms a continuous fringe outside the *Durvillæa* belt. It is chiefly of interest in that its large branched holdfasts, like the discoid holdfasts of *Durvillæa*, harbour a varied community of animals, and differences of opinion have been expressed as to the efficacy of drifting kelps in transporting these animals. The late Dr. Chilton used to emphasise the view, as finally stated in the "Subantarctic Islands of New Zealand" that faunistic similarities between New Zealand and South America are, at least predominantly, indication

of a former close geographical relationship, but later work, such as that of Dr. Mortensen on the echinoderms, emphasises rather the distributing agency of currents, which transport pelagic larvæ or drifting organisms. I have recently shown (*Rec. Cant. Mus.*, vol. 3, pt. 4, p. 255; 1930) that *Halicarcinus planatus* White, famed as the only circum-austral decapod, is a recent arrival in the South Atlantic, and its predilection for kelp is suggestive.

It would be of much interest to determine what proportion of the common elements in the marine fauna have such possible methods of distribution. Perhaps the members of the further expedition to the Antarctic next summer may have an opportunity of studying the fauna of kelp roots at Kerguelen Island, a certain half-way stopping place for drift from the west at least. The important point is the survival or otherwise of such animals after a voyage from the original reef to the place of stranding, and therefore it may be of interest to quote some such organisms which I have observed still alive on drift kelp on the New Brighton Beach, New Zealand. Such kelp, of course, has drifted for only a few miles. Apart from such organisms as *Lepas anatifera* and *Balanus decorus* on drifting wood, and many smothered animals embedded in the kelp holdfasts, such as *Mytilus planulatus*, *Terebratella rubicunda*, *Elminius modestus*, and many others, and miscellaneous polyzoans and sponges and others attached to the stipe or holdfast, and other animals such as *Halicarcinus tridentatus* not noticed alive on the stranded kelp, the following living organisms have been observed on stranded *Durvillæa*: the above barnacles, *Plaxiphora egregia*, *P. zigzag*, *Onithochiton neglectus*, *Saxicava australis*, *Irona reflexa*, *Calyptræa novæ-zelandiæ*, *Microlenchus tenebrosus*, *M. dilatatus*, *Mytilus planulatus*, *Lumbriconereis sphærocephala*. On *Macrocystis*: many of the above, also *Mytilus canalicus*, *Chlamys zelandiæ*, *Terebratella rubicunda*, *Elminius modestus*, *Chamæsipho columna*, *Limnoria segnis*, *Eulalia microcephala*, *Nereis amblyodonta*, *Trypanosyllis gigantea*. The last-named species has hitherto been known only from the southern islands. Some of these animals, chiefly the limpets, feed on the kelp, and hollow out the *Durvillæa* holdfast, which in old specimens is attached only round the rim.

Two further cases, not affecting geographical distribution, may be mentioned. The massive trough-shell *Spisula æquilateralis* is commonly stranded at New Brighton, no doubt through the agency of an epizoic hydroid which attains a length of more than a metre, and a smaller species, apparently undescribed, forms short, but dense, tufts on *Amphidesma forsteriana*, which occurs between tide marks on the same beach. It can survive burial in the sand, and indeed depends on the agility of the mollusc in burrowing to prevent the stranding of both, which, however, frequently occurs. The second case is one demonstrated to me by the late Mr. John Hardcastle, of Timaru, who showed me water-worn stones in a gully leading on to the shingle beach at Timaru, previously mentioned. The stones were too far from the beach to have been washed there, and too numerous to have been thrown by boys, and some were too deeply buried (though I did not verify this point) to have been ploughed under to that depth. Mr. Hardcastle believed that they were used by the seals (*Arctocephalus forsteri*) as ballast during former northern migrations, and regurgitated at this resting place. Corroborative evidence on this point would be of interest.

Inhibition and Mechanism of Photochemical Reaction in Eder's Solution.

A SYSTEMATIC investigation of kinetic aspects of the reaction in Eder's solution has revealed the fact that, although in a pure solution the reaction goes on in a somewhat different manner when it is subjected to the action of the X-rays [1] than under ordinary light rays, the difference is not an essential one and is due only to a faster rate of the reaction in the former case. Under the X-rays, for example, we do not observe an induction period, which is a conspicuous feature of light reactions; but if the intensity of the X-radiation is very small, the induction period is observed as usual. The presence of oxygen or increase in acidity tends to inhibit reactions in both cases.

If, however, the X-rays act in the presence of certain optical sensitisers, a striking difference is observed. I have studied reactions in the presence of ferric chloride, potassium permanganate, uranyl salts (nitrate and acetate), various fluorescent dyestuffs (uranin, eosin, erythrosin), and quinine bisulphate, and have found that these substances, all of which have a sensitising effect under the ordinary light, appear to be strong inhibitors when X-rays are used. Among them, potassium permanganate appears to occupy a peculiar position, for it undergoes a reaction itself under the influence of the X-rays (the solution changes its colour), and after the reaction has been completed, the inhibition stops and calomel begins to come down copiously from Eder's solution, which process goes on also in the absence of insolation.

Ferric chloride in small concentrations (c. 10^{-3} gm./c.c.) does not affect the rate of the reaction. But in concentrations from c. 10^{-2} gm./c.c. upward, it acquires the inhibitory power, and with the rise of concentration the rate of the reaction asymptotically falls to zero. These figures are quoted only to illustrate the orders of the magnitude involved, for actually the inhibiting action of ferric chloride is complicated by the influence of the concentration of dissolved oxygen. Uranyl salts act almost in the same way, though in this case the absorption of the X-rays increases very considerably, heavy atoms of uranium entering the solution. In this case even small concentrations produce the inhibition.

The behaviour of fluorescent sensitisers (dyes and quinine) is of still greater interest. A very small admixture of dye, quite inappreciable to the naked eye, is sufficient to produce a strong inhibitory effect. For example, erythrosin in concentrations of the order of 6×10^{-6} gm./c.c. delays the reaction by 64 per cent. The inhibitory property of all these substances increases at the same rate as their sensitising action under light. For example, uranin (sodium salt of fluorescein) has the weakest sensitising and inhibiting effect, whereas erythrosin is the most powerful in both directions.

In explaining these peculiarities it is natural to divide the substances into two groups according to the concentrations necessary to produce the inhibitory effect. The one group comprises ferric chloride and uranyl salts; dyestuffs and quinine belong to the other. The absence of sensitising effect in either group is accounted for by special conditions of X-ray absorption. The substances belonging to the first group owe their inhibitory property to a secondary effect, namely, to a considerable rise of hydrogen ion concentration as a result of hydrolysis of ferric chloride and uranyl salts. On the other hand, in the inhibitory effects of dyes and quinine sulphate, we have an obvious case of negative catalysis produced by traces of a substance.

According to Christiansen's theory, a negative

catalysis is good evidence of a chain reaction. Taking into consideration that free chlorine atoms, which are likely to arise in this case under the action of light (and X-rays),[2] enter very readily into chain reactions, we can argue that Eder's reaction is probably also a chain reaction, its mechanism being similar to that of the combination of hydrogen and chlorine. The available data in the literature, though not very exact, suggest that the quantum yield for Eder's reaction in any case is more than unity. By an indirect method, based on intensity of the inhibition, I can conclude that the length of the chain in this case is very considerable. E. SHPOLSKY.

Field Populations and Natural Control of *Lucilia sericata.*

SINCE the spring of 1929 I have been engaged at Toulouse on a study of the biological agencies which play a part in regulating numbers of the sheep 'blow-fly', *Lucilia sericata* Meign. The effect of parasites and predators was first sought by a quantitative study of the puparia derived from carrion in which the flies had bred. However, it soon became evident that the only way by which reasonable understanding could be obtained of the inter-relations of the various biological forms in the carrion and the magnitude of their action was by a quantitative study of the carrion insect populations, from the beginning of putrefaction to the disappearance of all consumable parts.

Suitable technique for obtaining a census of all species of the populations, both in the carrion and in the soil beneath it, has been developed by exposing simultaneously uniform baits of a number equal to the number of readings required, arranging to counteract any slight variation in bait attraction or field density and sacrificing a bait per census.

These quantitative studies have demonstrated the following points:

(1) The end result, taken at pupation or emergence, gives no indication of the magnitude of the reduction in numbers of *Lucilia sericata* by biotic agencies and little idea of the way in which the reduction is accomplished.

(2) Any significant effect which parasites and predators can have on the ultimate numbers of the fly surviving takes place after the bulk of the population has been destroyed by other means.

(3) The greatest factor in the reduction of the fly population within the carrion is Dipterous competition and its associated predatorism.

(4) The species concerned are, in addition to *L. sericata*, *L. cæsar*, *L. ampullacea*, *L. sylvarum*, *Calliphora erythrocephala*, *C. vomitoria*, *Sarcophaga* spp., and *Chrysomyia albiceps*.

(5) The magnitude of the competition and the fauna taking part differ according to the season, ather, and the type of bait used.

(6) There is in the insect fauna of carrion a definite ecological succession, comprising in the main the Diptera, species of Staphylinidæ, Silphidæ, Histeridæ, Hymenoptera, Dermestidæ, and Carabidæ, which, as regards the species concerned, varies according to the season. Within a family there may be species characteristic of an early stage in the succession and other species characteristic of a later stage.

(7) *Lucilia sericata* is the first member of this ecological succession and plays the part of a coloniser. Oviposition begins a few minutes after exposure in fresh meat or within a few hours of death in entire animals.

(8) All subsequent species of Diptera in the succession contribute to accentuate the competition and ultimately reduce the population of *Lucilia sericata*; the greatest reduction found has been that by the larvæ of Sarcophagids and the semi-carnivorous larvæ of *Chrysomyia*, both of which are most abundant during the summer, and the relative effect of which in carrion is largely determined by the type of bait used; the part played by Sarcophagids in meat baits is played by *Chrysomyia* in baits comprising entire animals (rabbits). The type and rapidity of putrefaction dependent on the kind of bait determines which of these forms gains the strongest hold and the ultimate ascendancy in the carrion.

(9) The part played by certain of the carrion beetles is negligible in the light of the part played by Dipterous competition, while the relation of forms, such as Histerids, more definitely associated with the Diptera during their late larval and puparial stages, is more significant. Dermestids are of little consequence to the fly population, for they are largely concerned with the drying carrion rather than with the Diptera.

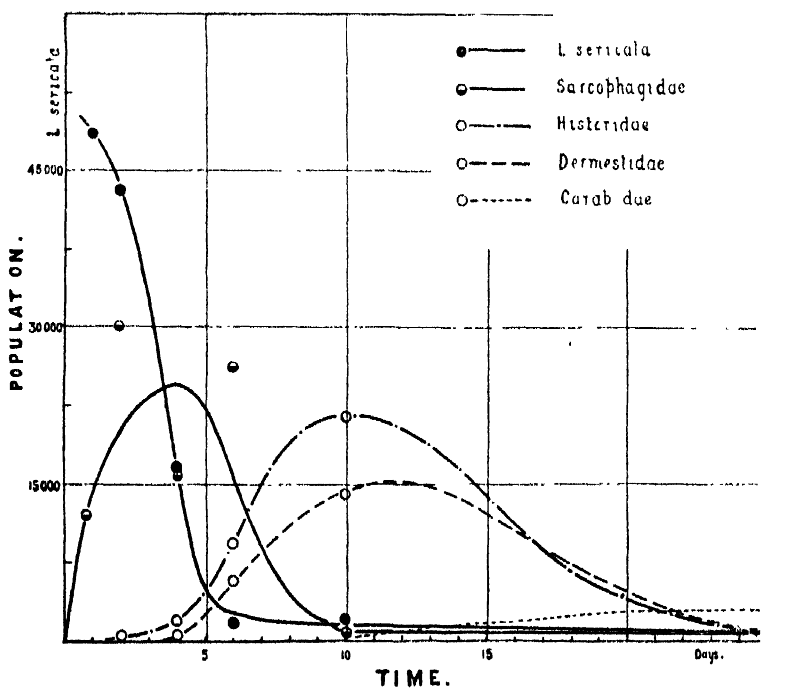

FIG. 1.—Graphic representation of carrion insect populations, showing ecological succession. (*L. sericata* scale on the left. Scale for other forms on the right.)

(10) No absolute idea can be obtained of the real effect of parasites or predators on the adult population of *Lucilia sericata* without an understanding of the inter-relations of the fauna of the carrion complex, particularly in the light of the differences associated with type of carrion, season, and also, no doubt, size of the carrion.

The accompanying illustration (Fig. 1) indicates

the type of results obtained. These particular results, given as live units, were secured under midsummer conditions in 1929; the bait, half a sheep's head laid on a piece of mutton, contained approximately 1 kgm. of consumable meat. The initial population of *L. sericata* was approximately 50,000 (the decreasing population twenty-four hours after exposure was 48,562), while the final field emergence was 231 flies. During the summer of 1930, under slightly hotter conditions, with a rabbit bait of approximately equal weight of consumable meat, and with *Chrysomyia* playing a rôle comparable to that of Sarcophagids in the former bait, an initial population of approximately 60,350 *L. sericata* plus 2850 *L. cæsar* yielded a final *Lucilia* population of 30 while the final *Chrysomyia* population was 2611.

Determination of the Abundance Ratios of Isotopes from Band Spectra.

IN band-spectroscopic determinations of the abundance ratio of isotopes, an important but hitherto neglected point of view appears as soon as one attempts to make any calculations of greater accuracy.

Suppose the isotopes A_1 and A_2 exist in the abundance ratio m. In molecular compounds with atoms B they will form molecules A_1B and A_2B also in the abundance ratio m. Now raising the temperature of the mixture, so that several vibrational states of the molecules come into play, this abundance ratio will not remain fixed for each state. Provided there is a thermodynamical equilibrium, the molecules will be distributed according to the Boltzmann expression $Ae^{-E/kT}$, where E, the vibrational energy of the molecules, is different for different isotopes.

Carrying out such calculations on boron monoxide, $B^{11}O$ and $B^{10}O$, at room temperature, the abundance ratio of their normal state ($v = 0$) is found to be approximately equal to m. But already in the first excited vibrational state ($v = 1$) this ratio is changed into $1{\cdot}3m$. From the Condon parabola of the intensity distribution in the β-bands of boron monoxide one finds by the aid of the Franck-Condon principle that transitions from the normal state ($v = 0$) chiefly will hit the first three vibrational levels ($v' = 0, 1, 2$) in the excited electronic state. A. Elliott (NATURE, **126**, 203; 1930) photographed this spectrum, using activated nitrogen as the source of emission. From intensity measurements on different plates he finds an approximately constant abundance ratio m for bands corresponding to transitions from $v' = 1, 2$ in the excited state. However, in bands corresponding to transitions from $v' = 3$ he finds a remarkable increase of 30 per cent in this value. This observation is in perfect agreement with our calculation above, as the population of molecules in the vibrational state $v' = 3$ is chiefly fed through collisions between active nitrogen and the boron monoxide molecules from $v = 1$ in the normal state. Moreover, the results of Elliott indicate that the Franck-Condon principle is valid also in this special case of low temperature, where the electronic transition is caused through collisions between particles of approximately equal masses.

Occasionally, Naudé's results on the determination of the abundance ratio of O^{16} and O^{18} (*Phys. Rev.*, **36**, 333; 1930) may be correct as based on intensity measurements of bands corresponding to transitions from the normal state $v = 0$ in the NO (β) spectrum.

Generally, however, correct values of the abundance ratio m from band-spectroscopic data afford determinations of m as a function of v, taking their weighted mean values from the energy distribution in the gas. Practically correct values are also obtained through intensity measurements on absorption bands belonging to $v = 0$ in the normal state, if the absorption gas is kept at low temperature.

Change of the Dielectric Constant of Ethyl Ether with Temperature.

I HAVE made a study of the dielectric constant of ethyl ether as a function of temperature with the aid of high frequency electromagnetic oscillations, using the method described by M. Wolfke and W. Keesom, *Comm. Leiden*, 190 *a*.

The construction of the measuring condenser has permitted the cooling of ethyl ether down to $-150°$ C. by the use of petrol ether as a cooling liquid, which was contained in a Dewar vessel, provided with a special refrigerator, cooled with liquid air. The uniformity of temperature throughout the substance under investigation was ensured by the use of a double stirrer and by the thinness of the layer of the cooling liquid. Temperatures were determined by means of

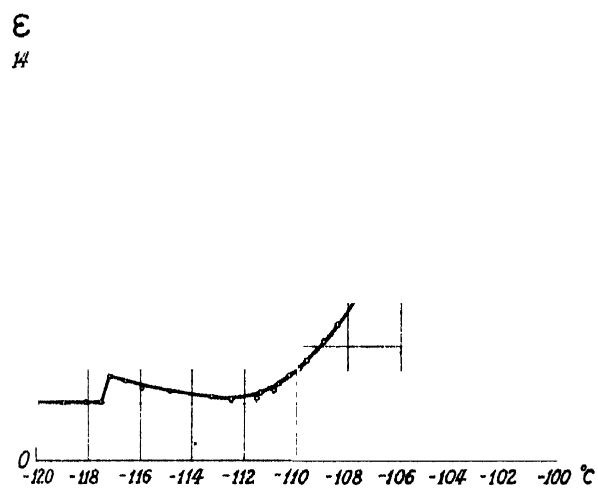

FIG. 1.

a platinum resistance thermometer, wound on the surface of the measuring condenser and calibrated with the aid of the normal thermometer of the Cryogenic Laboratory at Leyden.

The dielectric constant of very carefully purified ethyl ether increases with the lowering of temperature from 4·18 at 30·6° C. up to the highest value 12·39 at $-105{\cdot}4°$ C. and decreases very rapidly beyond that point. At the melting point, $-117{\cdot}2°$ C., there appears a distinct change in the dielectric constant, which was not observed by any of the previous workers. At temperatures lower than $-118{\cdot}9°$ the dielectric constant has a nearly constant value, equal to 2·04.

The changes of the dielectric constant of ethyl ether with the temperature described above are represented on the accompanying graph (Fig. 1).

The Scope and Aims of Human Geography.*

By Prof. P. M. ROXBY.

IT is to Ritter and Humboldt that we owe the real beginnings of human geography as an integral and, indeed, from Ritter's point of view, the crowning part of the subject matter. To appreciate the greatness of their work we must realise how critical for the whole future of geography was the period in which they lived. It was a period in which great masses of new geographical data were being accumulated, but so long as these remained unsystematised and unrelated, they tended only to increase the inchoate and amorphous character of a subject which was rather a torture to the memory than a stimulus to the mind. It was a period, too, in which many independent, specialised sciences dealing with particular aspects of earth lore such as geology and meteorology were rapidly developing so that the domain left to geography itself, according to the prevailing conception of its character, was increasingly uncertain. It was Ritter and Humboldt who rescued what seemed indeed to be a moribund subject and gave it coherence, individuality, and an immensely enhanced significance. This they did by claiming for it not a distinctive segment in the circle of knowledge—which is to destroy its very essence—but a distinctive method and objective in the handling of data common to other subjects. Ritter gave the keynote to the whole modern development of geography when he said (in his "Comparative Geography") "It is to use the whole circle of sciences to illustrate its own individuality, not to exhibit their peculiarities. It must make them all give a portion, not the whole, and yet must keep itself single and clear." Geography, he maintained, could only escape disintegration "by holding fast to some central principle; and that principle is the relation of all the phenomena and forms of nature to the human race".

The framework which the great pioneers of the early nineteenth century defined for the building up of a geographical synthesis, which in Ritter's view culminated in man's relationship to the earth, was sufficiently wide to permit of many converging contributions. Workers in many fields of geography were henceforth guided by the same fundamental principles and methods, and whether in geomorphology, in climatic or human geography, the central object became to exhibit the earth as a whole made up of related and interacting parts.

It is no doubt true that some of the workers in contributory fields have been initially trained in the special science which supplied the data, that is, have been in the first instance geologists or zoologists, but it is equally remarkable that many of them, when once they have acquired the geographical outlook have changed their objective and become primarily interested in placing or interweaving their contribution in the geographical synthesis as such. For it is from these main sources—geomorphology, climatic and biological (plant and animal) geography that we derive the data for building up that systematic geography of natural environments which is at once the objective of 'physical' geography and the starting-point of human geography.

The fundamental objectives of geography are the same to-day as those which the Greek philosophers of Asia Minor and Alexandria conceived. There is a 'modern geography' only in the sense that there has been a restatement of its scope and content in the light of all the new knowledge of the earth which more specialised branches of inquiry have revealed. It was the work of the great pioneers of the nineteenth century to disentangle it from these associated subjects and to ascertain the guiding principles through which and the means or technique by which contact and relationship with them could be most fruitful and helpful in the attainment of the ends for which all science stands. This clarification of its scope and methods was essential if geography was to be in a position to seize the opportunities for increased usefulness afforded by the conditions of the modern world. For the two circumstances which, granted vision and understanding on the part of its exponents, have inevitably enhanced the significance and value of our subject are surely these: that on one hand our more complete knowledge of the earth and of the distribution of phenomena over its surface has made it possible to formulate far-reaching and valuable generalisations as to their co-ordination and relationship for which the material had hitherto been lacking, and on the other that the rapidly increasing interdependence and inter-sensitiveness of the different regions and peoples of the planet have made a synthetic view of the world as of a whole made up of interrelated parts which is the prime object of geography—essential to human progress.

It is against this background of modern geography as a whole that the special aims and contributions of that part of it which we call human geography must be considered. The separate, departmental 'political geography' of the early nineteenth century is for ever discredited. Whatever value human geography may have is involved in its association with all the rest of the subject matter. It is on the question of the precise nature of the relationship that difference of view arises.

From the ranks of geographers themselves—as distinct from the views on the influence of natural conditions on human societies put forward from time to time by philosophers and economists such as Feuerbach, Engels, and Marx, or historians such as Buckle and Meyer—the two chief contributions have come from the school of thought associated with the name of Ratzel and that associated with the name of Vidal de la Blache.

* From the presidential address to Section E (Geography) of the British Association, delivered at Bristol on Sept. 5.

'Determinism' and 'possibilism' are the respective labels which have been attached to the two schools, and although labels, here as elsewhere, are liable to mislead, they sufficiently indicate a fundamentally different emphasis and attitude between the two in their treatment of the relationship of human societies to their natural environments. In the first or Ratzelian School the main emphasis is undoubtedly on the control of human activities by natural conditions, on the limitations which these impose, on the permanency of the stage, "always", as Ratzel insisted, "the same and always situated at the same point in space", and of the influences which it exerts, on the inevitability of particular developments, given a certain milieu. This attitude is even more pronounced in the works of some of the disciples of that other school of French human geographers or, as it is perhaps better to call them, geographical sociologists, who drew their inspiration from Le Play's "Les ouvriers européens", although Le Play himself cannot be identified with all their views. Geographical 'determinism' reaches its culmination in the "Comment la route crée le type social" of Demolins, who maintains that if history were to begin all over again it must in all essentials follow the same lines, given the same setting of the stage. Apart from the question of bias on the compelling power of physical circumstances, a criticism which has been levelled, as I think rightly, against the Ratzelian School, is that it is excessively dogmatic, and that, notwithstanding the vast amount of material which Ratzel himself and many of his disciples have sifted and classified with great skill, we are far as yet from having the data necessary for many of the big generalisations which they make.

The same criticism can certainly not be brought against Vidal de la Blache and his followers, whose discussions of these issues, while often extremely suggestive and illuminating, are rarely dogmatic or final in their conclusions or implications. The master himself did indeed deal in his larger works with what may justifiably be called 'principles' of human geography, but his teaching was always that the larger generalisations could only gradually emerge from a series of detailed and exact regional studies, and we shall all admit, I think, that his disciples have been very true to his precepts. The conception appears in the approach and particularly in the form even of the more ambitious work of Brunhes which bears the title "La géographie humaine". It is scarcely possible in a few sentences to characterise la Blache's concept of human geography, but I find its dominant note and one which brings it into salient contrast with the Ratzelian School in the following paragraph:

"L'être géographique d'une contrée n'est point une chose donnée d'avance par la nature, une offrande du monde inanimé ; elle est un produit de l'activité de l'homme, conférant l'unité à des matériaux qui, par eux-mêmes, ne l'ont point. . . . Si une contrée est une personne, c'est par l'effort de ceux qui l'habitèrent." The emphasis here and throughout his work is not so much on the determinative influence of the stage *per se*, although this is always presented as a vital factor, as on the creative power of human groups to adapt themselves to and, within limits, to mould the natural environment, to leave their impress upon it and thus in the course of generations to transform it and give it a personality which is the outcome of the interaction. This personality is not constant. It may change with man's use or abuse of his habitat.

With this indication of some dominant tendencies in the setting and perspective of human geography I pass to an attempt to define more closely its subject-matter and its different aspects. I believe that in essence human geography consists of the study of (*a*) the adjustment of human groups to their physical environment, including the analysis of their regional experience and of (*b*) inter-regional relations as conditioned by the several adjustments and geographical orientation of the groups living within the respective regions. The term 'adjustment' I take to cover not only the 'control' which the physical environment exerts on their activities but also the use which they make or can make of it. Human geography is the study of an interaction rather than of a control. The adjustment has distinct but usually closely related aspects which form the main branches of human geography. The relationship between them is from the geographer's point of view as intimate as that between the different branches of physical geography. The four principal aspects may be distinguished as the racial, economic, social, and political.

The racial aspect implies an adjustment of a different character from the others, one over which man has had little control but which he can increasingly influence through his better understanding of the issues involved. I am well aware that in touching on racial geography I am treading on dangerous and controversial ground. Yet I am convinced that it is as necessary to find the right relationship between human geography and anthropology as it is between physical geography and geology and that racial geography is as significant and essential a part of the geographical synthesis as is geomorphology. I think it is true to say that racial determinism, that is, the explanation of characteristics in terms of race alone, apart from environmental conditions, is becoming as discredited as geographical determinism, the explanation of everything in terms of physical environment.

The tendency in anthropology is certainly not in the direction of appraising racial types, so far as they can be definitely distinguished, according to an absolute scale of value or efficiency, but relatively to the geographical environments in which they are found. Their somatic traits are discussed in terms of regional adaptations and the fruitful hypothesis is put forward that so far from racial varieties being unchanging and fixed for all time they are continually undergoing slow modification and in process of becoming. Now the unit of the geographer's study is not race as such any more than it is climate as such or any other physical element. His unit is the place or region. It is this concept—and I do not think it can be emphasised too strongly—which gives distinctiveness and

individuality to his work. With the relationship of climate and other physical factors to race in a region, the geographer is closely concerned and there are few more important aspects of his study than the composition, actual or potential, of the societies occupying the region.

In the world of to-day there are many regions of 'closed' human associations, if I may borrow a useful term from plant geography, regions such as China or the Mediterranean lands as a whole where the dominant racial type or types in possession are so numerous and well adjusted that the entry of any important new racial element is extremely unlikely. But there are other regions of 'open' human associations, at present thinly peopled but capable of holding a much larger population, whose racial future is uncertain. Such, for example, are tropical Australia and parts of Malaya, of Africa, even of Asia. Is it possible or desirable for the geographer in his study of these regions to confine himself to their resources and economic possibilities and not to consider at all, in the light of all that he can learn from anthropology, the relative aptitudes and adaptability, climatic and otherwise, of various racial groups for developing them and the extent and manner in which co-operation between different groups may be secured for this end?

Take, for example, the highly important pronouncement made by General Smuts last autumn in one of his Rhodes' lectures at Oxford. In the course of his plea for the advance of native Africa through the introduction of a higher civilisation in the form of white settlement, he advocated "a strong forward movement in the policy of settling the highlands of Eastern Africa which stretch in an unbroken belt, hundreds of miles broad, from Kenya to South Africa". It is not for me to express an *a priori* opinion on the wisdom of this suggestion, but it raises vitally important issues of human geography.

These issues are at once racial and economic in character. Do we yet know enough about the effects of a high plateau climate in equatorial latitudes on peoples of North European stock? Even if it be granted that satisfactory acclimatisation of such peoples in the Kenya Highlands can be achieved, are the conditions of the plateau belt as a whole intervening between them and 'temperate' South Africa sufficiently similar to warrant the prospects of an equally good adjustment? The tentative generalisation has been made that, from the point of view of the success of 'white' plantations, there is a vital difference between the 4500/6000 feet altitude of the Kenya Highlands and other smaller mountainous 'islands' to the south and the 3500 feet level which seems to characterise most of Tanganyika. Or again, what are the prospects of making the 'fly belt' suitable for white settlement? Or, granted favourable climatic and other physical conditions, have the economic relations likely to be established between the proposed white settlers and the native Bantu tribes been sufficiently considered from the point of view of the uses which the two groups are likely to make of the land? It is not cartographical surveys alone—although these are vital and the basis of all others—which need to be made before such questions can be answered.

Similar questions arise concerning the future of southern Brazil, Malaya, parts of central and eastern Asia, and many other regions where groups with different racial characteristics and aptitudes are in competition. The racial aspect is only one of several, but the study of racial distributions, based on anthropological material in the same sense that geomorphology is based on geological material, seems an essential element in the content of human geography. Personally I feel it to be a distinct gain that, in at least one university, geography should be closely associated with anthropology, so long as it is not identified with it, just as in others it is more closely associated with economics or history or with physical science.

It is unnecessary for my present purpose to elaborate what is implied in that aspect of man's adjustment the study of which forms the subject-matter of economic geography. It is of course a fundamental and basic aspect, including the geography of production (with agricultural and industrial geography as its principal subsections) and the geography of exchange (commercial geography in the more technical sense).

Economic geography serves one of its highest functions if it is closely linked with other aspects of human adjustment to physical environment which have so far received less attention. Of these one of the most interesting and profoundly important is that which for want of a better term we usually call social geography. This may be broadly defined as the analysis of the regional distribution and interrelation of different forms of social organisation arising out of particular modes of life which themselves represent a direct response—although we may concede to M. Febvre not necessarily the only possible response—to distinctive types of physical environment. A classical example of the importance of this aspect is of course the age-long conflict between nomadic, patriarchal pastoralists and peasant cultivators, socially organised on a territorial basis, along the grassland borders of the hot deserts in Africa and Arabia and round the edges of the steppe-belt in Euro-Asia.

In modern times the problems connected with the interregional relations of differently organised groups in Africa and elsewhere have been greatly complicated by the impact of industrial Europe on their lives. It has particularly affected the traditional societies of intertropical Africa, the monsoon lands, and the South Sea Islands, where mode of life and social organisation, once established as an adjustment to their milieu, often remained in essentials unchanged until they were so suddenly, and in some cases so tragically, drawn into the maelstrom of modern commerce. In the last analysis this disturbance is one of the chief causes of world-wide unrest, since equilibrium with environment is the first essential of happiness for human groups.

One of the greatest needs of our time is to discover what for each type of regional environment or

milieu are the real factors in readjustment through which alone the recovery of equilibrium can be attained. What is involved is readjustment to all the local conditions of the habitat in the light of its new contact with other regions, its new place in the total scheme of world relationships. Modern Denmark would seem to be an admirable example of a successful readjustment of this kind. Statesmanship in such an Empire as ours is increasingly concerned with the task of harmonising the interests of many groups cradled in different environments, diverse in race, mode of life, and experience, but, under the conditions of the world to-day, increasingly interdependent. Particularly is this apparent in the problem of the readjustment of African societies, one of the most critical and complex of our time and one for the solution of which Great Britain has incurred heavy responsibilities. Such problems are as much geographical in character as those concerned with the regional planning of English districts, and equally demand detailed surveys by investigators capable of analysing the social life and experience of human groups in their whole geographical setting and of appreciating the significance of the new elements in their environment.

The modern tendency in geography to think of the earth in terms of natural as opposed to artificial divisions should not lead to the neglect of political geography in the proper sense of the term; for the function of political geography is to study and appraise the significance of political and administrative units in relation to all the major geographical groupings, whether physical, ethnographic, social, or economic, which affect mankind. It is essentially an aspect of adjustment to geographical environment, and it is precisely because it is so closely related to other aspects of adjustment, which in the influences that they exert are often conflicting, that equilibrium is so difficult to attain. The study of the mode in which geographical conditions have helped to mould the evolution of States in the past is of absorbing interest, however complex and difficult. The existence of favourable areas of characterisation possessing a considerable amount of natural protection, such as the English Plain and the Central Lowlands of Scotland, within which the social contact of orginally different racial and social groups was easy, certainly provided the medium through which in western Europe strong nation-States tended to take shape. The group consciousness which we call nationality seems to have followed rather than preceded the actual formation of such States. Nationality arose in relation to environment and widened its scope and allegiance with the increase of economic and political contact.

Since the forces promoting the contacts and economic interdependence of regions are operating on a much bigger scale in the world of to-day than ever before, we might expect to see this process of political integration even more strongly marked, and the rapid territorial growth of the United States and other large political entities can be quoted as examples of it. But in Europe we see this process arrested and even reversed.

Nationality, as tested by linguistic and cultural affinities, rather than the economic orientation indicated by the physical conditions, has been accepted as the main criterion of the new units, although there is frequent departure from this principle. The new Europe is admittedly a great experiment in political geography. Its success would seem to depend on the possibility of reconciling the different factors. The most stable political units are undoubtedly those which most correspond to geographical realities, but these realities are not wholly limited to considerations of physical and economic geography. The distribution of groups related in culture and language is also a geographical reality. The ideal State from the geographical point of view is one which neither divides groups culturally related nor interferes with the flow of trade along natural arteries and between regions economically interdependent. It may be, although as yet the indications are not very hopeful, that the urgent need of Europe for greater economic integration can be reconciled with the desire of the small nationality groups for cultural and political autonomy. It may be that economic federation or agreement among small sovereign-States within the framework of the League of Nations will prove the only alternative to the 'super-State' solution of the problem of European political geography propounded by Naumann in his "Mittel Europa". At any rate, nationality, considered apart from its geographical setting, may be a very dangerous conception.

I have tried to indicate the essential character of the principal aspects of human geography, each of them from the point of view of the adjustment of human groups to their geographical environment. It is permissible and desirable to pursue special studies of these various aspects of our subject, but they find their fullest fruition when they are brought together and inter-related in a full and comprehensive treatment of regions. We can never really appreciate the problems of such countries as India, China, and Russia until we have a comprehensive interpretation of their human ecology, to use the expressive term employed by the American geographer Barrows. In the future it is probable that geographical specialism in the universities will be less concerned with aspects (such as geomorphology, climate, and economic geography) —although this will always have its place—and more concerned with regions (the Mediterranean, tropical Africa, the Far East, and so on). The geographer's parish must indeed be the world, but it is too large a parish for all parts of it to be studied in detail by any one man. He must, if he is entrusted with a university department, delegate responsibility for as many regional chapels-of-ease as he can find associates and colleagues to work them.

We may claim for human geography that, rightly studied, it is a vital element in training for national and international citizenship. It can enable us "accurately to imagine the conditions of the great world stage" and the place of the different regions within it. It is a valuable mental discipline, calling

for an exact sense of proportion in appraising the value of many factors and more specifically developing the great quality of sympathetic understanding. The point of view and type of outlook which it fosters were never more needed than in the present critical stage of human development. Yet not only through its value as an educational instrument, but also through the programme of constructive work which it advocates, can it contribute to the realisation of the ideal of "unity in diversity", and that seems the only possible ideal for the life of humanity on a planet which, however small applied science may make it, will always retain its infinite variety.

Chemical Measurements by Colour.

By Dr. L. C. MARTIN.

IT is a pity that the word 'colorimeter' has been applied to two entirely distinct classes of instrument. The name is given most appropriately to those instruments which actually measure colour, albeit in relative terms, and not to those in which the chemical concentration of a solution is the subject of determination. The latter, which form the topic of the present article, are strictly colour comparators, and it would be an advantage if they could so be called. The alternative names chromometer and chromatometer also fail to give the proper indication, but would be preferable to 'colorimeter'.
